WATER.

WATER. This important fluid was believed by the ancients to be one of the four elements out of which they imagined every other substance is composed. This opinion maintained its ground for a very long period. At length, however, it began to be suspected, from the experiments of Van Helmont, Boyle, and others. Van Helmont shewed that plants would grow for a very long time in pure water; whence it was concluded that water was capable of being changed into all the substances found in vegetables. Mr. Boyle supposed, that by long digestion and boiling in glass-vessels, he had converted water partly into an earth. Margraaff, who repeated his experiment, drew the same conclusion; but the opinion was never very generally admitted, and at length was proved to be erroneous, the earth being shewn to be derived from the glass-vessels employed in the experiments.

The combustible nature of hydrogen gas was observed about the beginning of the 18th century, and the celebrated Scheele, many years afterwards, was the first who attempted to discover what was produced by this combustion. In this, however, he did not succeed; nor were Macquer, Bucquet, Lavoisier, Dr. Priestley, and others, who subsequently repeated the experiment with similar views, more fortunate. The distinguished honour of discovering the composition of water was reserved for Mr. Cavendish, who, in 1781, proved beyond a doubt that the combustion of hydrogen and oxygen produced this fluid, and nothing else. Water, therefore, since the period just mentioned, has been universally admitted to be composed of these two gaseous principles.

Water is found in abundance in every part of the globe, and is absolutely necessary for the existence of organized beings. When quite pure, as obtained by distillation, it is

Vol. XXXVIII.

perfectly transparent and colourless, and free from taste and smell.

A cubic foot of distilled water, according to the best experiments, weighs, at a temperature of 40°, 437102.4946 grains troy. Hence, a cubic inch of water at the same temperature weighs 252.952 grains; and at the temperature of 60°, 252.72 grains. The specific gravity of water is always supposed to be 1.000, and it is made the measure of the specific gravity of every other body. (See *SPECIFIC GRAVITY*, and *HYDROSTATICS*.) Water, at a temperature of 32°, becomes solid, and assumes the form of ice. In this state it possesses considerable hardness and elasticity, and its specific gravity is diminished to .94. See *FREEZING*, and *ICE*.

When water is raised to the temperature of 212° it boils, and is gradually converted into steam, which is an invisible and highly elastic fluid like air. The specific gravity of steam, according to the most recent observations, is .625, that of air being reckoned 1.000. See *BOILING*, *EBULLITION*, and *STEAM*.

Water is capable of undergoing a slight degree of compression. See *COMPRESSION*.

Water undergoes no alteration by exposure to heat or light. Thus it may be made to pass through a red-hot tube without suffering any change.

On exposure to the atmosphere, it absorbs a portion of air, the greater part of which is capable of being again driven off by boiling. To expel the whole, however, it is stated to be necessary to continue the operation at least two hours in a flask, with its mouth inverted over mercury. To this small proportion of air which it holds in solution, water chiefly owes its agreeable flavour, boiled water being insipid. See *ABSORPTION*, and *GAS*.

B

Hydrogen

Hydrogen gas, even at a red heat, has no action upon water. Charcoal, when cold, does not decompose it. But when red-hot charcoal is brought in contact with water, carbonic acid and carburetted hydrogen are formed in abundance. Sulphur and phosphorus do not appear to be capable of decomposing water, even when assisted by heat; but potassium and sodium, and doubtless also the metallic bases of the alkaline earths, decompose it rapidly. Of the other metals, iron, zinc, antimony, and tin, decompose it, when assisted by heat. Silver, gold, copper, and platina, produce no effect upon it.

Water dissolves the alkalies and alkaline earths. The acids also, and many saline compounds, are soluble in this fluid; but it is incapable of dissolving the earths properly so called.

Water combines with bodies in two different ways. It either dissolves them, in which case the proportion of water is unlimited, or it combines with them, and forms solid compounds, termed *hydrates*, into the composition of which the water enters in a definite proportion. The metallic hydrates, in general, are remarkable for the brilliancy of their colours. They are more soluble in acids than the oxyds, and in some instances affect the organs of taste even more perceptibly than the metallic salts. This subject has been particularly investigated by M. Proust. See *HYDRATE*.

According to the latest and most perfect experiments, water is composed of two volumes of hydrogen gas, and one volume of oxygen gas. Hence, its combining weight or atom will be 1.125, oxygen being reckoned 1; or, if we consider the specific gravity of hydrogen gas to be .6944, and of oxygen gas 1.1111, it is composed of one part by weight of hydrogen, and eight parts by weight of oxygen. The union of oxygen and hydrogen gases to form water is attended by the extrication of much light and heat. See *COMBUSTION* and *DETONATION*.

WATERS, Natural. "Water," says Dr. Saunders, "is found throughout the earth in every degree of purity, except the highest, for such is never procured, except by artificial distillation, as all natural waters are constantly coming into contact with some substance which they can either dissolve or hold suspended." Waters to which the epithet *mineral* is applied, in many instances differ from other natural waters in the degree only in which they are impregnated with similar foreign substances: in other instances, they differ in the nature of the impregnating ingredient; but for the most part they differ in both these circumstances. In presenting our readers with an account of natural waters in general, we shall commence with an enumeration and short account of the different foreign ingredients usually met with in waters, and influencing their operation on the animal economy.

1. *Caloric.*—The temperature of natural spring-waters is the same, in general, as the mean annual temperature of the particular place in which they occur. It is evident, therefore, that this temperature must vary with the latitude. (See the articles *CLIMATE*, *TEMPERATURE*, &c.) Waters rarely occur of a temperature much lower than the mean annual temperature of the latitude in which they are found; but instances are met with in every part of the globe in which they occur of a higher temperature. This degree of increased temperature is very different in different instances. Commonly it is not very striking, while in other cases it is very remarkable: thus, the waters of Carlsbad, in Bohemia, have the extraordinary temperature of 165°. In this country, the hottest springs are those of Bath and Buxton, the highest temperatures of which are stated to be 116° and 82° respectively. In some instances, these deviations from the natural temperature are obviously referrible

to the neighbourhood of volcanoes, but generally their cause is very obscure, as we can hardly form any idea of agents operating for such a length of time, and so uniformly, as those of necessity must do which give origin to the phenomena in question: all we can infer is, that although local, they are deep-seated and permanent.

2. *Atmospheric Air: Azote.*—All natural waters of a mean temperature hold a portion of common air in solution. The quantity, however, has been stated by Bergman not to exceed $\frac{1}{10}$ th of the bulk of the water; and even this can only be retained at a mean temperature, and under the ordinary pressure of the atmosphere, for the greater part of it escapes under the air-pump, or on submitting the water for a short time to a temperature of 212° or 32°. It is the oxygen contained in this small portion of atmospheric air, retained by water, that supports the respiration of fishes, and other aquatic animals, which speedily die from suffocation in water deprived of air. It is this air also, as before observed, which renders water sapid and grateful to the palate; for by boiling or distillation, this fluid is rendered insipid and disagreeable, "and has long been in disrepute," says Dr. Saunders, "for lying heavy on the stomach, and even producing scrofulous tumours and obstructions." The presence of atmospheric air in water is easily accounted for, from the affinity which subsists between the two substances, and which is such, that they soon become mutually impregnated by being exposed to each other.—Azotic gas has been found to exist in small quantity in some waters, and in these instances it has been observed to be extricated from the spring itself in union with the water. As far as is at present known, this gas imparts no medicinal or even sensible property to the waters containing it.

3. *Carbonic Acid.*—This gas is likewise stated by Bergman to exist in greater or less quantity in all natural spring-waters. The limits in which it occurs is said to lie between about $\frac{1}{1000}$, and an equal bulk of the water. In mineral waters it is a most important ingredient, not only from its operation upon the animal economy, but from its being the solvent of various other active ingredients. When waters contain this principle in excess, they assume a bright and sparkling appearance to the eye, have an agreeable pungent acidulous taste, and sometimes exert a kind of intoxicating power when largely drunk. Fishes are unable to exist in them, and speedily die from suffocation. On exposure to the air, however, these properties in a short time become sensibly diminished, and at length almost totally disappear, owing to the separation of the gas—an operation which may still more speedily be effected by boiling. The presence of this gas in water is easily explained, from its natural affinity to that fluid. In almost every instance it is extricated from the spring in union with the water; but the source from whence it is derived is, in general, obscure and inexplicable.

4. *Hydrogen and its Compounds, carburetted, sulphuretted, and phosphuretted Hydrogen.*—Hydrogen gas is barely soluble in water, and probably, therefore, never exists alone in that fluid. The same is true of carburetted hydrogen. Both these gases, however, are often extricated from waters, especially when stagnant, and containing organic substances in a state of putrefaction. Sulphuretted hydrogen is a frequent ingredient in mineral waters, and gives them so characteristic a feature, that they are instantly recognized. Waters holding this gas in solution have an offensive smell, like that of rotten eggs, or a foul gun-barrel, and which is more or less strong, according to the degree in which they are impregnated. Such waters also have a taste somewhat sweetish, and they generally appear turbid. Water, at a mean

mean temperature, is stated to absorb from $\frac{2}{3}$ ds to $\frac{1}{4}$ ths of its bulk of this gas, and by long agitation more than its bulk. At a temperature of 80° or 90° , however, this fluid can with difficulty be made to dissolve any of it. Sulphuretted waters, therefore, on exposure to heat, or even to the open air without heat, soon lose their characteristic properties, and become turbid, the hydrogen being dissipated, and the sulphur deposited. The source of this gas, in general, is not obscure, it being formed in great abundance during the decomposition of pyrites, and other minerals containing sulphur. Phosphuretted hydrogen is said to be occasionally extricated from marshes and stagnant pools, but it is not known to constitute an ingredient in mineral waters.

5. *The Alkalies and their Salts.*—The fixed alkalies seldom, if ever, occur in natural waters in a free state. Even the number of their salts is so limited, that Dr. Saunders thinks it necessary to enumerate only two, namely, the sulphate and muriate of soda. The first of them is a very common ingredient in mineral waters, but rarely occurs alone in any quantity, so that it can hardly be said ever to give a peculiar character to a water. Muriate of soda is so extensively and abundantly diffused through nature, that we rarely meet with a natural water which does not contain more or less of it. Sea-water, and many natural waters or *brines*, owe their peculiar characters to this salt, which has been known from the earliest times, and seems to be almost a necessary ingredient in our food. The muriate of soda, however, never occurs alone in natural waters, but is commonly accompanied by some of the earthy salts, especially the sulphate of lime. Chemists have been puzzled to account for the origin of the vast quantity of this salt which is met with in the sea and elsewhere; but a little reflection will shew, that the existence of this substance is not more difficult to be accounted for than that of any other ingredient of our globe. From its property of being soluble in water, it is, perhaps, more generally diffused than any other principle; but it is doubtful if it actually exists in greater abundance than silica, and many other solid substances, and which, in a geological point of view, differ from it only in the mechanical circumstance of their insolubility in water. The carbonate of soda is occasionally met with in waters. Its distribution, however, is very partial, being usually in very minute quantities, or in very large ones. When in small quantity, it is generally supersaturated with carbonic acid. The most remarkable instance of an excess of this salt is in “the natron lakes of Upper Egypt. It is here often mixed with common salt, and they both are largely dissolved in the water, and form a crust of several feet in thickness at the edge of the lake, owing to the copious evaporation of their water of solution effected by a tropical sun.” Potash, or its salts, very seldom occur in mineral waters. Carbonate of ammonia is occasionally found in small quantities in some waters, arising probably, as Dr. Saunders conjectures, from decomposed animal or vegetable substances.

6. *The Earths and their Salts.*—The earth most frequently occurring in natural waters is lime, and so generally is this the case, that very few instances are known in which this earth is not met with in some state or other. The neutral carbonate of lime, or *chalk*, is one of the most insoluble substances known; but the supercarbonate of lime is very soluble, and is a frequent ingredient in many springs. “It is one source of *hardness* in waters,” says Dr. Saunders, “but is easily got rid of by boiling, which drives off the excess of carbonic acid, and thus causes the chalk to be precipitated; hence the earthy crust or *furr* on

kettles in which hard water has been boiled for a number of times. Some natural waters contain an unusual quantity of this calcareous earth, which is rapidly deposited as soon as they become exposed to the air, and thereby give an earthy lining to every tube through which they flow, and encrust with the same material every substance that accident or design may put in their way. Of this kind are the various petrifying springs that form part of the natural curiosities of several mountainous districts, and have been applied to use in a very ingenious manner at the baths of St. Philip, in Tuscany, and still more extensively at Gualecavelica, in Peru.”—“The sulphate of lime (the gypsum or selenite of the older writers) is one of the commonest of all the earthy salts that are found in natural waters, and generally accompanies every saline substance, except where there is an excess of alkali. It is almost invariably found in conjunction with the carbonate of lime; and hence the calcareous depositions, petrifications, and the like, frequently contain a small admixture of selenite.” This salt imparts very little taste to water, but gives it “that rough and harsh feel to the fingers and tongue, which characterize the insipid *hard* waters.” The muriate of lime commonly accompanies the other salts of lime, but especially the muriate of soda. When in excess in any water, it imparts to it a bitter and disagreeable taste, and active medicinal properties. The great bitterness of “the waters of the Dead sea is owing to the muriates of lime and magnesia, and not to bitumen, as was erroneously supposed.” The carbonate of magnesia is insoluble in water; the supercarbonate of magnesia, when it occurs in waters, is always accompanied by the supercarbonate of lime, both the earths being held in solution by an excess of carbonic acid. The supercarbonate of magnesia, however, is more soluble than the supercarbonate of lime, and is not, therefore, so easily separated by boiling. The sulphate of magnesia, or *Epsom* salt, as it was formerly denominated, is the most important of the salts of this earth. It almost always accompanies the sulphate of soda; and to these two salts most of the natural purging waters owe their cathartic properties. It is likewise frequently combined with the sulphate of lime, and also with iron. The sulphate of magnesia imparts to the waters containing it in any considerable quantity a strongly bitter and saline taste. It was first discovered in a spring at Epsom, whence its name; but is usually prepared at present from the refuse salt of sea-water, after the common salt has been separated. The muriate of magnesia, as before-mentioned, commonly accompanies the muriates of soda and lime; hence it is found in various brine-springs, and forms a considerable part of the saline contents of sea-water, to which fluids, especially when concentrated by evaporation, it imparts a strong bitter taste. Salts of alumina are not of very frequent occurrence in waters. The most common is the superphosphate of alumina, or common alum, which is usually associated with the sulphate of iron. The source of this salt is for the most part alum-slate, the sulphur contained in which becomes acidified on exposure to the air, and forms sulphuric acid, which, uniting with the alumina, produces the salt in question. The presence of the sulphate of iron is easily accounted for upon similar principles, since more or less of iron pyrites almost invariably accompanies alum-slate. Silica, in a state of minute division, is sometimes found suspended in small quantity in running waters, but is soon deposited on their remaining at rest. This earth, however, occasionally occurs in a state of solution in hot and tepid springs, especially in the neighbourhood of volcanoes. The menstruum appears to be usually a little free or carbonated alkali, the solvent

powers of which are doubtless much increased by heat, or by some unknown cause.

7. *Metals and their Salts.*—The metal most usually met with in natural waters is iron; never, however, in its metallic state, but in a state of oxyd combined with an acid. The carbonate of iron is a frequent ingredient of natural waters, the base of which is the black or protoxyd of the metal, for the red oxyd does not seem capable of combining with carbonic acid, or at least of forming with it a soluble compound. This is, doubtless, a wise provision of nature; for, as Dr. Saunders justly observes, if the contrary were the case, almost every natural water would be a chalybeate. The carbonate of iron, like all the other salts of this metal, imparts to waters containing it a peculiar inky taste, “which,” says Dr. Saunders, “is very perceptible, even when the proportion of iron is so small as hardly to be estimable by any chemical process.” Waters containing the carbonate of iron deposit this metal readily on exposure to the air, partly from the escape of the carbonic acid, and partly from the further oxydation of the metal. The sulphate of iron or green vitriol is met with occasionally in waters in considerable quantity. This salt, as before observed, generally occurs in union with the sulphate of alumina, or alum, and is the natural production of the decomposition of iron pyrites. Waters containing this salt in any quantity, possess the properties of chalybeates in a high degree, and are peculiarly styptic. The muriate of iron is occasionally met with in natural waters; but its existence in any considerable quantity is a rare occurrence. *Copper*, or rather its salts, and especially the sulphate of copper, is occasionally met with in natural waters. This generally, however, occurs in the neighbourhood of copper-mines; and the sulphate of copper, as Dr. Saunders observes, is probably formed, like the sulphate of iron, by the decomposition of copper pyrites. Waters containing this metal are highly poisonous, and are never used internally. *Manganese* is occasionally found in small quantity in natural waters. It appears, in general, to be associated with iron; but the state in which it exists is not accurately known. As far as present observation goes, it imparts no sensible or other properties to the waters containing it. *Lead*, perhaps, never naturally occurs in waters; but some waters have the property of dissolving, or holding in suspension, a minute portion of this pernicious metal, when exposed to it in the metallic state. Pure soft waters are said to possess this property in the most striking degree.

8. *Mineral Acids.*—Both the muriatic and sulphuric acids are occasionally met with in mineral waters in a free state. Such springs usually occur in volcanic countries.

9. *Bitumen.*—Bitumen is said by many of the older writers to be a frequent ingredient in mineral waters. This statement, however, has been generally found erroneous by modern chemists, who have in most cases demonstrated the supposed bituminous principles of their predecessors to be substances of a very different nature. There are some springs, however, which yield a real bitumen; but this, from its insolubility in water, is never dissolved in that fluid, except in a few rare instances, through the medium of an alkali.

Such is a short account of the principal mineral substances which are met with in natural waters when they issue from the earth. “When,” says Dr. Saunders, “they flow within a channel over the surface of the ground, they often become much changed in their chemical composition, losing some of their contents by evaporation, others by slow deposition, or by being decomposed through the influence of light and air. At the same time they often acquire new

contents, which are furnished by the soil over which they flow. Thus the streams which pass over a country covered with vegetable matter, or which water large towns, will contain a sensible quantity of mixed alluvial contents, or a heterogeneous compound of animal and vegetable extract of mucilage.

Different authors have chosen different principles of arrangement in treating of natural waters. An arrangement purely chemical, or purely medicinal, cannot be effected in the present state of our knowledge; we shall not therefore attempt either, but shall consider them under the following heads:

1. Potable waters.
2. Saline waters.
3. Chalybeate waters, simple and compound.
4. Acidulous waters, simple and compound.
5. Sulphurous waters, simple and compound.
6. Thermal waters, simple and compound.

This arrangement of natural waters, according to their *sensible* properties, coincides likewise, as well perhaps as the present state of the subject will admit, with their *chemical* and *medicinal* properties. It may, however, be objected to the divisions *simple* and *compound*, that neither of them is accurately correct, and this must be admitted in a strictly chemical point of view; but taken in the enlarged and general sense here understood, there seems to be no serious objection to this mode of division.

1. *Potable Waters.*—Under this division we wish to include every variety of this fluid ordinarily used by mankind and other animals for satisfying their thirst. These may be comprehended under the heads of, *a*, pure or distilled water; *b*, atmospheric water; *c*, spring-water; *d*, running water; and *e*, stagnant water.

a. The chemical properties of pure water have been already described at the head of this article. As before observed, it never occurs in nature, and was therefore probably never intended as an article of drink for mankind; certainly, at least, not as one absolutely necessary for their existence, or even healthy condition.

b. Under *atmospheric* waters are included rain-water, snow-water, dew, &c.

Rain-water, collected at a distance from large towns, or any other object capable of impregnating the atmosphere with noxious materials, approaches more nearly to a state of purity than perhaps any other natural water. Even collected under these circumstances, however, it invariably yields traces of the muriatic acid, and, according to Margraaff, of the nitric also. Rain-water of course differs according to the state of the atmosphere through which it passes. “The heterogeneous atmosphere of a smoky town,” says Dr. Saunders, “will communicate some impregnation to rain as it passes through; and this, though it may not be at once perceptible on chemical examination, will yet render it liable to spontaneous change: and hence rain-water, if long kept, especially in hot climates, acquires a strong smell, becomes full of animalculæ, and in some degree putrid.” Rain-water in general, in warm climates, is much more impure and liable to become offensive than in cold and temperate ones. Rain also that falls in the spring and summer, or after a long-continued drought, or very hot weather, is said to be more impure than that which falls at other seasons of the year, or after a long-continued moist season; circumstances, doubtless, owing to the existence of a greater proportion of animal and vegetable principles in the atmosphere in such climates and seasons. These foreign substances have sometimes been so abundant and peculiar in their appearance, as

to have given origin to many marvellous stories, such as the raining of blood, &c. (See the article RAIN.) The specific gravity of rain-water hardly differs from that of distilled water; and from the minute portions of the foreign ingredients which it generally contains, it is very soft, and admirably adapted for many culinary purposes, and various processes in different manufactures and the arts.

Snow-water equals, if not surpasses, rain-water in purity, when collected under the same circumstances, it being for obvious reasons more free from animal and vegetable impregnations; thus Dr. Ruttly found it perfectly sweet after keeping it in a close vessel for eighteen months. Snow-water, like rain-water, even in its purest state, yields traces of muriatic acid, and perhaps also of the nitric.

Hail-water may be compared to snow-water, which it closely resembles: indeed

Ice-water in general is very pure, as the air and saline substances are separated by freezing. Common ice-water, however, is less pure than rain and snow water, as the foreign substances, though perhaps separated by freezing, still remain incorporated with the ice, so that it is impossible to melt the ice without retaining at least a portion of these foreign matters.

Dew, being deposited chiefly from the lower parts of the atmosphere, is commonly much more impure than rain or snow water. According to Dr. Ruttly's observations, it soon becomes fetid and offensive. It yields also more sensible traces of the presence of muriatic acid than rain-water. This fluid, however, collected at different places and times, differs exceedingly in its properties, as might be naturally expected.

c. Spring-water includes *well-water*, and all others that arise from some depth below the surface of the earth, and which are used at the fountain-head, or at least before they have run any considerable distance exposed to the air. Although all spring-waters are originally of atmospheric origin, yet they differ from one another according to the nature of the soil or rock from which they issue; for though the ingredients usually existing in them are in such minute quantities as to impart to them no striking medicinal or sensible properties, and do not render them unfit for common purposes, yet they modify their nature very considerably. Hence the water of some springs is said to be *hard*, others *soft*, some *sweet*, others *brackish*, &c. according to the degree and nature of the impregnating ingredients. Common springs pass insensibly into mineral or medicinal springs, as their foreign contents become larger or more unusual; or in some instances they derive medicinal celebrity from the absence of those ingredients usually occurring in spring-water; as, for example, is the case with the Malvern and other springs. Almost all spring-waters possess the property termed *hardness* in a greater or less degree. This hardness, as we formerly mentioned, depends chiefly upon the sulphate and carbonate of lime which they hold in solution. The quantity of these earthy salts varies very considerably in different instances; but Dr. Saunders observes, that when they exist in the proportion of five grains in the pint, such water will be hard, and from its property of decomposing soap will be unfit for washing, and many other purposes of household use or manufactures. The water of deep wells, according to Dr. S., is always, *ceteris paribus*, much harder than that of springs which overflow their channel; but there are many exceptions to this rule. The *softness* of spring-waters depends on their containing smaller proportions of the earthy salts above-mentioned. Spring-waters are said to be brackish, when they contain a small proportion of the muriates of soda, magnesia, or lime, as is frequently the case in the neighbourhood of the sea.

Sweetness is generally understood as opposed to *brackishness* or *factor* when applied to spring-waters. The specific gravity of spring-waters in general is greater than that of distilled or any other potable water. See SPRING.

d. Running waters include *river-waters*, and every other species of water exposed to the air, and moving in an open channel. On this part of our subject we cannot do better than quote from Dr. Saunders. "River-water," says Dr. S., "in general is much softer, and more free from earthy salts than spring-waters, but contains less air of any kind; for by the agitation of a long current, and, in most cases, a great increase of temperature, it loses common air and carbonic acid, and with this last much of the lime which it held in solution. The specific gravity thereby becomes less, the taste not so harsh, but less fresh and agreeable, and out of a hard spring is often made a stream of sufficient purity for most of the purposes where a soft water is required. Some streams, however, that arise from a clean silicious rock, and flow in a sandy or stony bed, are from the outset remarkably pure, such as the mountain lakes and rivulets in the rocky districts of Wales, the source of the beautiful waters of the Dee, and numberless other rivers that flow through the hollow of every valley. Switzerland has long been celebrated for the purity and excellence of its waters, which pour in copious streams from the mountains, and give rise to some of the finest rivers in Europe."—"Some rivers, however, that do not take their rise from a rocky soil, and are indeed at first considerably charged with foreign matter, during a long course, even over a richly cultivated plain, become remarkably pure as to saline contents, but often fouled with mud and vegetable or animal exuvia, which are rather suspended than held in true solution. Such is that of the Thames, which, taken up at London at low water, is very soft and good water, and after rest and filtration it holds but a very small portion of any thing that could prove noxious, or impede any manufacture. It is also excellently fitted for sea-store, but it here undergoes a remarkable spontaneous change. No water carried to sea becomes putrid sooner than that of the Thames. When a cask is opened, after being kept a month or two, a quantity of inflammable air (carburetted or sulphuretted hydrogen) escapes, and the water is so black and offensive as scarcely to be borne. Upon racking it off, however, into large earthen vessels, and exposing it to the air, it gradually deposits a quantity of black slimy mud, becomes clear as crystal, and remarkably sweet and palatable. The Seine has a high reputation in France, and appears, from the experiments of M. Parmentier, to be a river of great purity. It might be expected that a river which has passed by a large town, and received all its impurities, and been used by numerous dyers, tanners, hatters, and the like, that crowd to its banks for the convenience of plenty of water, should acquire thereby such a foulness as to be very perceptible to chemical examination for a considerable distance below the town; but it appears from the most accurate examination, that where the stream is at all considerable, these kinds of impurity have but little influence in permanently altering the quality of the water, especially as they are for the most part only suspended, and not truly dissolved; and therefore mere rest, and especially filtration, will restore the water to its original purity. Probably, therefore, the most accurate chemist would find it difficult to distinguish water taken up at London from that procured at Hampton-court, after each had been purified by simple filtration." The water of the Ebro also, notwithstanding this river passes through several large towns, is remarkable for its purity. In general, those rivers which issue from lakes are most pure and transparent, while those chiefly supplied

supplied by springs and rain are the reverse. The water of some rivers is remarkable for its colour: thus that of the Tinto, in Spain, at its source is of a fine topaz, a circumstance from which the river takes its name. Others are of a yellowish or greyish-white, and the water of all such rivers usually holds a large proportion of some salt of lime in solution. In countries where bogs and marshes abound, the rivers are often tinged of a brownish colour.

e. Stagnant Waters.—Under this head are included the waters of lakes, pools, and reservoirs of every description, in which this fluid is exposed to the air in a state of rest. Stagnant waters, in general, present greater impurities to the senses than any others, from their usually containing a large proportion of animal and vegetable matters in a state of decomposition. Their taste in general is vapid, and destitute of that freshness and agreeable coolness which distinguish spring-water. Stagnant waters have various origins, but usually they are a mixture of rain, spring, and river water; and hence, besides the animal and vegetable matters they contain, may be supposed to be impregnated with the various saline matters usually met with in such waters. Many stagnant waters are said to contain the nitrate of potash; others, and especially some lakes, abound in the sulphate of magnesia; others in the carbonate of soda, as, for example, the natron lakes of Egypt and Hungary, which are generally very shallow. A lake in Thibet is impregnated with the borate of soda mixed with the muriate of soda, the waters of which seem to have a subterranean origin. Some lakes also are found impregnated with sulphuretted hydrogen gas. Stagnant waters are seldom perfectly colourless and transparent. Lakes, when deep, are usually of a blueish tinge, mixed with green; and when the neighbouring hills are covered with peat, &c. their water is always of a muddy-brownish tinge, as, for example, is the case with most of the lakes in Scotland.

1. *Uses of Potable Waters.*—If we were to be directed by the evidences of the senses alone, *spring*-waters would undoubtedly be pronounced to be the most wholesome, for they are universally admitted to be the most agreeable. All other waters have more or less of a flat insipid taste. This is especially the case with *distilled* and *rain* water; the first of which is quite pure, and the second nearly so. *Distilled* water, therefore, is seldom employed for drinking; and the difficulty of procuring it in large quantities almost precludes its use to any extent in the preparation of food, or in manufactures. Much, however, has been lately said of its medicinal powers by Dr. Lambe, who has recommended it in cancerous and other affections; and, as Dr. Saunders justly observes, water, when not already loaded with foreign matters, may become a solvent for concretions in the urinary passages; and as much good has been obtained from the use of very pure natural springs, a course of distilled water may be considered as a fair subject of experiment. *Distilled* water is an essential ingredient in the composition of many medicines, and often absolutely necessary in the prosecution of all nicer chemical processes in the liquid way. *Snow* and *ice* water form almost the constant drink of the inhabitants of cold climates during winter; and the masses of ice which float on the polar seas afford an abundant supply of fresh water to the mariner. “*Snow-water*,” says Dr. Saunders, “has long lain under the imputation of occasioning those strumous swellings in the neck which deform the inhabitants of many of the Alpine valleys; but this opinion is not supported by any well-authenticated indisputable facts, and is rendered still more improbable, if not entirely overturned, by the frequency of the disease in Sumatra, where ice and snow are never seen, and its being quite unknown in Chili and

Thibet, though the rivers of those countries are chiefly supplied by the melting of the snow with which the mountains are always covered.” *Dew*, especially when collected in the month of May, was formerly in great repute as a cosmetic, and for many other purposes; but its use has been long entirely laid aside. *Spring*-waters, as before observed, from the air they contain, and from their grateful coolness, constitute by far the most agreeable of the potable waters, and are in more general use than any others. Their use, however, is stated sometimes to occasion in delicate stomachs an uneasy sense of weight, followed by a degree of dyspepsia. They have also been accused, especially when of the description termed *hard*, of inducing calculous affections; but this notion by most modern writers is considered as ill-founded. *Spring*-waters, in general, also, from their property of hardness, are, as before observed, very ill adapted for many domestic and other purposes; while, in particular instances, this quality is of advantage. *Hard spring*-waters, for example, are very ill adapted for the purposes of the dyer or bleacher. “On the other hand,” says Dr. Saunders, “there are several saline substances which are very readily soluble in any kind of water, and here a hard water may be employed when the object is only to procure these particular salts. For culinary purposes, water is used either to soften the texture of animal or vegetable matter, or to extract from it, and present in a liquid form some of its soluble parts. Soft pure water will fulfil both these objects better than hard water; and at the same time the colour of the substance employed will vary as well as its solution. Green vegetables and pulse are rendered quite pale, as well as tender, by boiling in soft water; whereas in a hard water, the colour is more preserved, and the texture less altered, because in the former case the colouring matter of the vegetable is readily extracted by the menstruum, whilst in the latter more of it remains, and is likewise altered by the chemical action of the earthy or neutral salts.” Dr. S. then relates some comparative experiments he made with hard and pure water upon tea; from which he concludes that hard water is less powerful in softening the texture of vegetable leaves than soft water, and that it is not able to exert its full effect in heightening their colour till assisted by heat; and also, that the gallic acid (or tannin) is equally well extracted by hard as by soft water, when by raising the temperature, the power of the former as a solvent is fully exercised. It may be therefore laid down as a general rule in domestic economy, that when the object is to extract the virtues of any substance, and to retain them in solution, *soft* waters should be used; but that when the object is the reverse, or to preserve as entire as possible the article used as food, *hard* waters are preferable.

Some fine springs of very pure and soft water have been long celebrated for their medicinal properties; as, for example, the *Malvern* springs, in Worcestershire, and *St. Winifrid's Well*, at Holywell, in Flintshire. *Malvern* water is used both externally and internally. Externally applied, it is stated to be a most useful application to deep-seated ulcerations of a scrofulous nature, and to various cutaneous affections. Its internal use is often of advantage “in painful affections of the kidneys and bladder, attended with the discharge of bloody, purulent, or fœtid urine; the hectic fever produced by scrofulous ulcerations of the lungs, or very extensive and irritating sores on the surface of the body; and also fistulas of long standing, that have been neglected, and have become constant and troublesome sores.” The internal use of this water sometimes induces nausea at first, and occasionally drowsiness, vertigo, and head-ache, which soon go off, or may be readily removed by a mild purgative,

WATER.

purgative. This water occasionally purges, but most commonly the body becomes costive under its use. "In all cases, it increases the flow of urine, and improves the general health of the patient; so that his appetite and spirits almost invariably improve during a course of the water, if it agrees in the first instance." The duration of a course of this water depends in a great degree upon the nature of the disease under which the patient labours. These observations upon the effects of the Malvern water are perhaps equally applicable to all spring-waters of a similar degree of purity.

What has been said of spring-waters may be applied perhaps with little modification to *running* waters, which in general differ from *spring*-waters only in being softer, in containing less air, and in being therefore better qualified for many purposes for which spring-waters cannot be employed. *Stagnant* waters in general, especially in marshy countries and hot climates, are usually esteemed unwholesome, and perhaps deservedly so. This arises chiefly from the large quantity of vegetable and animal exuviae which they contain, and perhaps from other circumstances of which we are at present ignorant. They should never be used, therefore, till they have been boiled and filtered; by which processes most of the foreign substances will be probably removed. In general stagnant waters, as Dr. Saunders observes, are unpalatable; and this circumstance has probably caused them to be sometimes in worse credit than they actually deserve to be on the score of salubrity.

2. *Simple saline Waters.*—Under this denomination we include all those waters impregnated with neutral, alkaline, and earthy salts only. Waters of this description may be arranged under the following heads:—*a.* Brines, or waters whose principal saline ingredients are the muriates of soda and magnesia; and *b.* Bitterns, or waters containing principally the sulphates of soda and magnesia.

a. Sea-water, which may be considered as an example of the saline waters termed brines, is one of the most abundant and extensively diffused compounds occurring upon our globe. When taken up at a considerable distance from the shore it is quite transparent and colourless, and free from any smell. Its taste is strongly saline, and at the same time nauseous and bitter. When kept for a short time it becomes highly offensive, from the putrefaction of the animal and vegetable matters which it holds in solution. Its specific gravity varies in different latitudes and circumstances, but may be said to lie between 1.0269 and 1.0285. The specific gravity is said to be less within the polar circles than at the tropics, owing probably to the vast quantities of ice found in those regions. The waters of inland seas also, that have little connection with the ocean, and the water of bays, &c. into which fresh-water rivers empty themselves, contain in general less saline matters than the open ocean. This is particularly the case with the Baltic, especially when the wind blows from the east. The Mediterranean sea, on the contrary, is said to be more saline than the Atlantic. Water taken from a considerable depth is more saline than that taken from the surface, particularly after much rain, for rain-water being lighter appears to move upon the surface for a considerable time before it becomes quite incorporated. The quantity of saline matter also is stated to be greater in summer than in winter. The water of the British coasts is said to contain upon an average about one-thirtieth of its weight of saline matter, and its temperature to vary between 40° and 65°. Sea-water does not freeze till cooled down to 28.95°. The following is one of the latest analyses of sea-water by Dr. Murray. A

wine pint of water collected in the Firth of Forth was found to contain

	Grains.
Of lime	2.9
Magnesia	14.8
Soda	96.3
Sulphuric acid	14.4
Muriatic acid	97.7
	226.1

Or, supposing the elements to be combined in the modes in which they are obtained by evaporation; that is, as muriate of soda, muriate of magnesia, sulphate of magnesia, and sulphate of lime, the proportions of these salts in a pint will be,

	Grains.
Muriate of soda	180.5
— of magnesia	23.0
Sulphate of magnesia	15.5
— of lime	7.1
	226.1

Or, supposing that the lime exists as muriate of lime, (which is the most probable conclusion with regard to it); and farther, supposing that the sulphuric acid exists in the state of sulphate of magnesia, the proportions will be,

	Grains.
Muriate of soda	180.5
— of magnesia	18.3
— of lime	5.7
Sulphate of magnesia	21.6
	226.1

Or, lastly, supposing that the sulphuric acid exists in the state of sulphate of soda, the proportions will be,

	Grains.
Muriate of soda	159.3
— of magnesia	35.5
— of lime	5.7
Sulphate of soda	25.6
	226.1

The bitter taste of sea-water is owing chiefly to the muriate of magnesia which it contains. It may also arise, in part, from the presence of decayed vegetable and animal substances. See the articles SALT, SALTNESS, and SEA.

Many attempts have been made to render sea-water potable. Of these the best, and indeed the only good one, is distillation.

The method of obtaining fresh water from the distillation of sea-water was practised by sir R. Hawkins, in the reign of queen Elizabeth, who thus obtained water that was wholesome and nourishing. See Purchas's Collect. of Voyages, book vii. chap. 5.

Experiments were afterwards made by Hales, Lister, Hanton, Lind, and others, to simplify and render more perfect the process of distillation, and at length it attained a great degree of perfection, both in France and England. Thus M. de Bougainville, in his Voyage round the World, bore ample testimony to the utility of the machine for distilling sea-water, which had been made public in 1763 by M. Poissonnier, its inventor; and lord Mulgrave, in his Voyage

Voyage towards the North Pole, in 1773, did equal justice to the method of obtaining fresh water from the sea by distillation, which had been introduced into the English navy in 1770, by Dr. Irving, and for which he obtained a parliamentary reward of 5000*l*.

Dr. Irving's contrivance consisted in converting the ship's kettle into a still. Every ship's kettle is divided into two parts, by a partition in the middle; one of these parts is only in use when peas or oatmeal are dressed, but water is at the same time kept in the other, to preserve its bottom. Dr. Irving availed himself of this circumstance; and by filling the spare part of the copper with sea-water, and fitting on the lid and tube, shewed that sixty gallons of fresh water could be drawn off, during the boiling of either of the above-mentioned provisions, without the use of any additional fuel. He recommended also the preserving of the water distilled from the coppers in which peas, oatmeal, or pudding, are dressed, as both a salutary beverage for the scorbutic, and the most proper kind of water for the boiling of salt provisions. Dr. Irving particularly directed that only three-fourths of the sea-water should be distilled, as the water distilled from the remaining concentrated brine was found to have a disagreeable taste; and as the farther continuation of the distillation proved injurious to the vessels. For an account of the several experiments made on some of the best distilled water, prepared by Dr. Irving from sea-water, by Dr. Watson, see his *Chem. Ess.* vol. ii. p. 163, &c.

The ships of discovery lately sent out by the French government are furnished with an economical distilling apparatus, and instead of water have taken with them a supply of fuel.

Dr. Priestley suggested a plan to give to distilled water the briskness and spirit of fresh spring-water, and at the same time to render it, perhaps, a remedy or preventive against the scurvy, by impregnating it with carbonic acid gas. Distilled water also acquires, in a considerable degree, the grateful flavour of common water, by simple exposure for some time to the atmosphere.

Sea-water may be likewise rendered potable by converting it into ice. In the polar regions, therefore, there can be no want of fresh water. In warm climates, the ingenious freezing apparatus of Mr. Leslie may be employed to procure a supply of fresh water from the ocean.

b. As an example of the bitters we may select the *Sedlitz water*, which is one of the best known, and strongest of this description of simple saline waters. Sedlitz is a village in Bohemia, and its waters, as well as those of Seydschutz in the immediate neighbourhood, and which closely resemble them, were first brought into note about a century ago by the celebrated Bergman. The taste of these waters is strongly bitter and saline, but not in the least brisk or acridulous, as they usually contain a small proportion of gaseous matters. Thus the Seydschutz water above-mentioned was found by Bergman to yield only 6 per cent. of gaseous products, two-thirds of which only were carbonic acid. Its specific gravity, as stated by the same chemist, is 1.006, and an English wine pint was found to contain of

		Grains,
Carbonate of lime	-	.944
Sulphate of lime	-	5.140
Carbonate of magnesia	-	2.622
Muriate of magnesia	-	4.567
Sulphate of magnesia	-	180.497
		193.770

Sulphate of soda is not mentioned as an ingredient in this water, although it doubtless exists in it; at least this salt almost always occurs in waters of this description.

Medicinal Properties and Uses of the simple saline Waters.—

All waters of this description act more or less strongly upon the bowels, according to the quantity of saline ingredients which they contain; hence they are often of the greatest use in complaints where alvine evacuations are particularly indicated. They generally act also as diuretics. Sea-water and all brines have the property of inducing a sensation of thirst. "Sea-water," says Dr. Saunders, "when used internally, should be taken in such doses as to prove moderately purgative, the increase of this evacuation being the peculiar object for which it is employed: about a pint is generally sufficient, and this should be taken in the morning, at two doses, with an interval of about half an hour between each. It is seldom necessary to repeat the dose at any other time of the day. This quantity contains half an ounce of purgative salt, of which about three-fourths are muriate of soda."—"There is very little danger ever to be apprehended from an excessive dose of sea-water, except the inconvenience of a temporary diarrhoea, and sometimes a foreness at the extremity of the rectum, which all saline purgatives are now and then apt to produce." The internal use of sea-water, besides its general use in diseases where cathartics are indicated, has been recommended in various forms of scrofulous affection, especially in indolent glandular tumours in the neck and other parts, which are commonly slow in ulcerating and in their cure; also in deep-seated scrofulous inflammations, followed by caries of the bones, profuse discharges, and tedious exfoliation, and particularly in scrofulous ophthalmia. "In all such cases, the internal use of sea-water is almost entirely confined to those periods of the disease when there is no general fever and hectic tendency, when no symptoms of danger are present, and when the object is rather to prevent a relapse than oppose any present disease. The external use of sea-water either as a general cold bath, or as a topical application to indolent swellings, or granulating ulcers, when the healing process has commenced, coincides perfectly well in these cases with the general intention." The most important advantages of sea-water are indeed probably derived from its external use as a bath. (See the articles BATH and BATHING.) With respect to the medicinal properties of the bitters, we shall attempt to illustrate them by relating those of the Sedlitz water, which we before selected as an example of the whole tribe. A pint of this water, taken in divided portions, is generally a full dose for an adult, and the strongest person seldom requires more than two pints. It operates very speedily, and without producing griping or flatulency; and is stated by Hoffmann, as quoted by Dr. Saunders, to be of the utmost advantage in a foul state of the stomach, and general torpor of the intestinal canal, as it not only stimulates these organs to expel their morbid contents, but by its bitterness restores their tone, and with it the appetite and digestive powers. "When the presence of hypochondriasis is marked by anxiety, general languor, perturbed dreams, a livid hue on the face, difficulty of breathing, pain of the back and head, vertigo and coldness of the extremities; when a bilious humour and a depraved secretion of the stomach impairs its tone and healthy action, and is attended with obstinate costiveness; this water, by evacuating its contents and restoring the due force of contraction, enables it to throw off the offending matter."—"Numerous trials also have shewn the efficacy of this saline water in that cachexy of females attended with a suppression of the menstrual discharge, whereby

WATER.

whereby are produced a general languor, difficult respiration, febrile heat and irritation, wasting of the body, and loss of appetite. Also when women have arrived at that time of life when this periodical evacuation begins to cease, and is succeeded by a number of anomalous disorders, such as prostration of appetite, flatulent pains, irregular flushings, pains in the back and swelling of the feet, a course of Sedlitz water restores the wavering appetite, and disperses the tumours and other morbid symptoms. Men of from forty to fifty years of age, who have led a very sedentary life, and have been accustomed to intense thought and profound meditation, become frequently affected with œdematous tumours in the extremities, a want of due action in the stomach, eructations after taking food, and a generally impaired state of health; all of which are for the most part very certainly removed by a liberal use of this water. Persons also of a plethoric habit of body, who from some obstruction of blood in the abdominal viscera, and have acquired a strong disposition to hæmorrhoidal affections, become thereby often exposed to very serious evils. To such persons a saline water like that of Sedlitz is often of great utility, especially if accompanied by blood-letting when requisite, and a general antiphlogistic plan of cure. Another important use of these waters is in removing from the system those impurities and acrid humours which are usually termed scorbutic." Such are the properties of the Sedlitz saline waters according to the celebrated Hoffmann, whose account, as quoted by Dr. Saunders, we have extracted, because it presents in few words a comprehensive and rational view of the medicinal properties of this important tribe of waters in general. We wish however to observe, that when the stomach is in a very weak state, and dyspepsia is present in a very great degree, saline purgatives and waters in general may do harm by increasing these affections; their use, therefore, in such cases is rather contra-indicated, or at least should be combined with other remedies calculated to invigorate these organs, especially chalybeates.

3. *Simple chalybeate Waters.*—Chalybeate waters are either *simple* or *compound*. Under this head of *simple chalybeates* we include all waters whose characteristic ingredient is one or more of the neutral salts of iron. These may be considered as of two general descriptions:—*a.* Waters containing the carbonate of iron, without any striking excess of carbonic acid; and *b.* Waters containing the sulphate or muriate of iron, generally in combination with a large proportion of the sulphate of alumina. Waters of this last description are much more rare than the former, and are usually formed from the decomposition of iron pyrites.

a. As an example of the first of these varieties of simple chalybeate waters, we may adduce that of Tunbridge Wells. This water has been lately submitted to a careful and accurate analysis by Dr. Scudamore, from whose pamphlet on the subject we chiefly take the following account. The temperature of the spring throughout the year is uniformly 50°; and its sp. gr. in the month of August, at its natural temperature, was 1.0007. The fresh water is perfectly transparent, and does not send forth air-bubbles. It exhales a smell which is distinctly chalybeate. Its taste in this respect is strongly marked, but is neither acidulous nor saline. It has an agreeable freshness, and is by no means unpalatable. Submitted to analysis, one gallon was found to contain,

	Cubic Inches.
Of carbonic acid	8.05
Oxygen	.50
Azote	4.75
	13.30

	Grains.
Of muriate of soda	2.47
———— of lime	.39
———— of magnesia	.29
Sulphate of lime	1.41
Carbonate of lime	.27
Oxyd of iron	2.29
Traces of manganese, insoluble mat- ter (vegetable fibre, silicæ, &c.)	.44
Loss in processes	.13
	7.69

Or, stating the results according to Dr. Murray's view, which will be particularly explained when we treat of the *analysis* of mineral waters, the following estimate will appear:

	Grains.
Muriate of soda	1.25
Sulphate of soda	1.47
Muriate of lime	1.54
———— of magnesia	.29
Carbonate of lime	.27
Oxyd of iron	2.29
Traces of manganese, &c.	.44
Loss, &c.	.13
	7.68

This latter estimate, which renders the carbonate of iron the most abundant ingredient in the water, appears much more probable than the former, and to account more satisfactorily for its medicinal effects.

b. One of the most striking examples of the second variety of simple chalybeate waters is that occurring in the Isle of Wight, and lately analysed by Dr. Marcet. This spring issues from a cliff on the S.S.W. side of the isle, immediately under St. Catherine's Down, in the parish of Chale, between which village and the village of Niton it is nearly equidistant. The distance from the sea-shore is about 150 yards, and elevation about 130 feet above the level of the sea. Its properties, &c. are the following:—When it first issues from the rock it is perfectly transparent, and remains so if kept in close vessels; but when exposed to the air, reddish flakes are soon deposited in it. It has a slight chalybeate smell, and a highly astringent and styptic taste. Its specific gravity, in a course of several experiments, was found to be 1007.5. One pint or sixteen-ounce measures yielded

	Grains.
Of carbonic acid $\frac{1}{3}$ ths of a cubic inch,	
Sulphate of iron, in the state of crystal- lized green sulphate	41.4
Sulphate of alumina, a quantity of which, if brought to the state of crystallized alum, would amount to	31.6
Sulphate of lime dried at 160°	10.1
Sulphate of magnesia crystallized	3.6
Sulphate of soda crystallized	16.0
Muriate of soda crystallized	4.0
Silica	0.7
	107.4

This therefore is the strongest aluminous chalybeate known.

Medicinal Properties and Uses of simple chalybeate Waters.—*a.* The season for drinking the Tunbridge water, which we have selected as an example of the simple carbonated chalybeates,

WATER.

lybeates, is usually from May to November. On entering upon the use of this water some aperient should be premised; and Dr. Scudamore recommends that the first dose should be taken at seven or eight o'clock in the morning, the second at noon, and the third about three in the afternoon. The exact quantity to be taken must be varied according to circumstances; but "as a general statement," says Dr. S., "I would say that half a pint daily is the extreme smallest quantity, and that two pints daily is the extreme largest amount to found a just expectation of benefit; and further, in the way of general outline of direction, I conceive that half a pint, a pint, a pint and a half, and two pints, should form the progressive ratio of the total daily quantity to be taken at the three intervals. As the patient arrives at the larger proportions, they may with advantage be subdivided with the interval of a quarter or half an hour, which should be occupied in exercise." Tea at breakfast is directed to be avoided; and in cases when the water disagrees at its natural temperature, it is recommended to be administered warm. "On the first employment of the water, either cold or warm, some inconvenient sensations very commonly arise, such as flushing of the face, slight fulness of the head, with drowsiness and an uneasy distension of the stomach, together with continued flatulence. In general these effects are not of importance, either in degree or duration, and are much to be prevented by previous attention to the stomach and bowels." — "As a general statement, it may be added, that the employment of this water is improper in a very plethoric state of the circulation; also when there is an inflammatory determination to any particular organ, or even when local congestion exists without inflammation. In cases of simple debility of the constitution, the water promises to produce its happiest effects. The proofs of its immediately agreeing with the patient are increased appetite and spirits, and these auspicious symptoms are followed by a gradual improvement in the general energy and strength." The bowels usually become constipated under its use, and require the assistance of medicine. The warm bath is occasionally of service in conjunction with this water, as was long ago pointed out by Hoffmann. Exercise also after its use is generally of great importance. In dyspepsia depending on debility of the stomach, and accompanied with general languor and nervousness, this water is remarkably restorative. In uterine debility also, and chlorosis, its use is often of the utmost service. It has been much recommended likewise in some cutaneous affections. For the

complaints of children, especially when young, (that is to say, under six or seven years of age,) it is not in general adapted, for reasons sufficiently obvious. A course of this water may vary from three weeks to two or three months, according to circumstances. *b.* With respect to the medicinal properties of waters containing the sulphates of iron and alumina, as the Isle of Wight and Hartfell waters above-mentioned, they differ little perhaps, except in degree, from those of the simple chalybeate waters. The Isle of Wight water is so strong, that it is always proper to dilute it at first with twice its quantity of common water; and even then the dose cannot well exceed two or three ounces, which may be gradually increased to about a pint in twenty-four hours. Dr. Saunders recommends the same quantity as the maximum dose of the Hartfell water. Both these waters are often much improved by being gently heated, especially in cases where the stomach is very delicate and irritable. Dr. Lempriere, who has written a pamphlet on the Isle of Wight water, states, that he found it particularly serviceable in the debility induced by the Walcheren fever, chronic dysentery, &c. as well as in every instance when the constitution had been undermined by previous illness, and the ordinary tonics had failed. It is particularly necessary to guard against costiveness during the use of these waters.

Compound Chalybeate Waters.—These may be divided into *a.* Saline chalybeates, and *b.* Acidulous chalybeates.

a. The Cheltenham waters, properly so called, are a good example of the *saline chalybeates*. (For the history of these waters, see CHELTENHAM.) Since that article was written, however, several springs of different qualities and powers have been discovered by Mr. Thomson; an abstract of the composition and properties of which, as lately published, we shall now take the opportunity of laying before our readers.

The springs which have been described and analysed by Messrs. Brande and Parkes are six, *viz.*

1. The strong chalybeate saline water. Sp. gr. 1009.2.
2. The strong sulphuretted saline water. Sp. gr. 1008.5.
3. The weak sulphuretted saline water. Sp. gr. 1006.
4. The pure saline water. Sp. gr. 1010.
5. The sulphuretted and chalybeated magnesia spring, or bitter saline water. Sp. gr. 1008.
6. Saline chalybeate, drawn from the well near the laboratory.

The following Table presents a view of the contents of a wine pint of these different springs.

Springs.	1	2	3	4	5	6
Muriate of soda	41.3	35.0	15.0	50.0	9.5	22.0
Muriate of magnesia	—	—	—	—	9.0	—
Sulphate of soda	22.7	23.5	14.0	15.0	—	10.0
Sulphate of magnesia	6.0	5.0	5.0	11.0	36.5	—
Sulphate of lime	2.5	1.2	1.5	4.5	3.5	—
Carbonate of soda	} 1.5	—	—	—	—	—
Oxyd of iron		0.3	0.5	—	0.5	1.5
Loss	—	—	—	—	1.0	0.5

Sulphuretted hydrogen	—	2.5	2.5	—	1.5	—
Carbonic acid	2.5	1.5	1.5	—	4.0	10.0
Total	2.5	4.0	4.0	0.0	5.5	10.0

WATER.

The medicinal properties of these different springs of course vary according to their composition and strength. Mr. Thomson, the proprietor, procures from them six different saline preparations, neither of which, however, is precisely similar to the water drank at the spa. These he denominates, crystallized alkaline sulphates; ditto effloresced and ground to an impalpable powder for hot climates; magnesian sulphate in a state of efflorescence; a murio-sulphate of

magnesia and iron in brown crystals, highly tonic; sub-carbonate of magnesia in powder, and calcined magnesia.

b. As an example of the *acidulous chalybeates*, we may adduce the celebrated waters of Spa. (See SPA.) Dr. Jones has lately published an interesting paper on these waters, which contains, among other things, analyses of the different springs, of the results of which the following table presents a summary view.

TABLE exhibiting the Nature and Proportion of the Substances contained in One Gallon of the respective Spa Waters.

Fountains.	Temperature.	Specific Gravity.	Carbonic Acid Gas. Cub. In.	Solid Contents. Grains.	Sulphate of Soda.	Muriate of Soda.	Carbon. of Soda.	Carbon. of Lime.	Carbon. of Magnesia.	Oxyl of Iron.	Silex.	Alumina.	Loss.

* Quantity not appreciable.

With respect to the medicinal properties of the compound chalybeates, they are, as might be expected, of a mixed character, and usually correspond with the nature of the predominant impregnating ingredients; hence their properties will be readily understood from what has been advanced. For further particulars respecting the medicinal properties of the CHELTENHAM and SPA waters, we refer our readers to these articles.

4. *Simple Acidulous Waters.*—Under this denomination may be included all waters whose characteristic ingredient is an acid. They may be considered as of two descriptions: a. Those impregnated with a volatile acid, as the carbonic and sulphurous acids; and b. Those containing a fixed acid, as the muriatic and sulphuric acids.

a. The waters of Seltzer may be adduced as an example of the first variety of acidulous waters. "Seltzer is a village situated in a fine woody country, about ten miles from Frankfort, and thirty-six from Coblenz, in a district which abounds with valuable mineral springs." This water has been examined by Hoffmann, Bergman, and others. When fresh from the well, it is perfectly clear and pellucid, and sparkles much when poured into a glass. Its taste is slightly pungent, but at the same time gently saline and alkaline. On exposure to the air for a short time, the carbonic acid escapes, and the alkaline taste becomes more per-

ceptible. According to Bergman, an English pint contains of

Carbonic acid upwards of	Cub. Inches.
	17
Carbonate of lime about	Grains.
Carbonate of magnesia	3
Carbonate of soda	5
Muriate of soda	4
	17.5
	29.5

b. Waters containing a free mineral acid in excess are very rare, and chiefly confined to volcanic countries. Mr. Garden has lately examined a water of this description from White island, on the coast of New Zealand: it was of a pale yellowish-green colour; its odour resembled that of a mixture of muriatic and sulphurous acids. Its taste was strongly acid and styptic, like that of a chalybeate. Its specific gravity 1.073. On being submitted to analysis, its contents were found to consist chiefly of muriatic acid, a slight trace of sulphur, small proportions of alum, muriate of iron, and sulphate of lime. Waters impregnated with sulphuric

fulphuric acid are sometimes met with likewise in the vicinity of volcanoes.

As to the *medicinal properties* of these waters, they probably differ little from those of a dilute solution of the different acids which they contain. For the particular properties of the Seltzer water, see SELTZER.

Compound Acidulous Waters.—Acidulous waters sometimes contain so large a proportion of saline matters, that the nature of their operation is considerably modified. Such waters may be denominated *saline acidulous* waters. The nature of their *composition* and *medicinal properties* will be readily understood from what has been already advanced.

5. *Sulphureous Waters.*—These are either *simple* or *compound*. A good example of a *simple* sulphureous water is the Moffat spring. The village of Moffat is situated in Dumfriesshire, on the banks of the Annan, about fifty miles south-west of Edinburgh. The sulphureous waters for which this village is noted, issue from a rock a little below a bog, whence, says Dr. Saunders, they probably derive their sulphureous ingredient. This water, even when first drawn, appears somewhat milky. Its taste is sulphureous, and slightly saline. It sparkles a little when poured from one glass into another. On exposure to the air, it becomes more turbid, and throws up a thin film, which is pure sulphur, and it thus loses its distinguishing properties as a sulphureous spring. This change even takes place in close vessels, so that it cannot be exported with any advantage. According to Dr. Garnett's analysis, a wine pint of this water contains

	Cubic Inches.
Of sulphuretted hydrogen	1.25
Of carbonic acid	.625
Of azote	.5
	<hr style="width: 50px; margin-left: auto; margin-right: 0;"/>
	2.375

And of muriate of soda 4.4 grains.

With respect to the *medicinal properties* of simple sulphureous waters, they have been always celebrated for their good effects in cutaneous affections in general, and also in scrofula. They are applied externally in the form of a warm bath, as well as taken internally. They have been also recommended in bilious complaints, dyspepsia, general want of action in the alimentary canal, and calculous cases. The quantity of the Moffat waters usually prescribed internally varies from one to three bottles every morning. But Dr. Saunders justly observes, that few delicate stomachs can bear so much. On the other hand, the same eminent physician informs us, that the common people not unfrequently swallow from six to ten English quarts in one morning.

For further particulars respecting this spring, see MOFFAT.

Sulphureous waters frequently contain so considerable a proportion of saline substances as to merit the name of *compound*. An example of such waters we have in the celebrated springs of Harrowgate, in Yorkshire. (See HARROWGATE.) This water, when first taken up, appears perfectly clear and transparent. It emits a few air-bubbles. Its smell is very strong, sulphureous, and fœtid, like that of a foul gun-barrel. Its taste is bitter, nauseous, and strongly saline; though it is remarkable that most persons soon become reconciled to it. On exposure to the air, it becomes turbid, the sulphureous odour is diminished, and the sulphur is gradually deposited. According to Dr. Garnett, its spe-

cific gravity is 1.0064. A wine pint, according to the experiments of the same chemist, was found to contain about

	Cubic Inches.
Of sulphuretted hydrogen	2.375
Carbonic acid gas	1.000
Azote	.875
	<hr style="width: 50px; margin-left: auto; margin-right: 0;"/>
	4.25

And of

	Grains.
Muriate of soda	76.9
Muriate of lime	1.6
Muriate of magnesia	11.4
Carbonate of lime	2.3
Carbonate of magnesia	.7
Sulphate of magnesia	1.3
	<hr style="width: 50px; margin-left: auto; margin-right: 0;"/>
	94.2

With respect to the *medicinal properties* of waters of this description, and particularly of Harrowgate water, they are of the greatest use in all those complaints that require purgatives, and at the same time are benefited by sulphur; hence they have been long celebrated in cutaneous affections, in piles, worms, &c. They have also been found of great use in that obstinately costive habit of body which usually accompanies hypochondriasis. Harrowgate waters were formerly principally applied externally, but now they are generally recommended to be taken internally, in such doses as to produce a sensible effect upon the bowels; for which purpose it is commonly necessary to take in the morning three or four glasses, of rather more than half a pint each, at moderate intervals.

6. *Thermal Waters.*—There is something so mysterious and remarkable in the circumstances of thermal springs, that they have in all ages attracted great attention, and been supposed to possess extraordinary medicinal properties. Hence, by most writers on mineral waters, thermal springs have been arranged under a distinct head; and as there appears to be no serious objection to this arrangement, we have thought proper to adopt it. The investigation of the *cause* of thermal springs belongs to the geologist, and will be found under EARTH, HOT SPRINGS, TEMPERATURE, VOLCANO, and analogous articles.

They may be divided into *simple* and *compound*.

Simple thermal waters are either *tepid*, that is, possessing a temperature below that of the human body; or *warm*, possessing a temperature above that point. A good example of the simple tepid waters are those of Buxton. (See BUXTON WATER.) *Tepid* waters usually occur in lime-stone districts. *Warm* waters of every degree of temperature, even to the boiling point, are occasionally met with in the neighbourhood of volcanoes. See VOLCANO.

With respect to the *medicinal properties* of the simple thermal waters, it is extremely doubtful if they possess any other powers than those of common water artificially raised to the same temperature.

Thermal springs are liable to be impregnated with all the different substances which usually enter into the composition of cold mineral waters; hence they are very various in their nature. Such *thermal* waters may be called *compound*, and without any great sacrifice of the principles of arrangement we have adopted, may be comprised under three heads; namely, *a.* Saline thermal waters, *b.* Acidulo-chalybeate thermal waters, and *c.* Sulphureous thermal waters;

WATER.

waters; each of which varieties may be either *tepid* or *warm*.

a. Thermal waters simply *saline* are very rare. Their properties can in no respect be supposed to differ from cold saline waters raised to the same temperature. Sea-water, therefore, heated artificially, is a good example of this variety. It is generally used externally as a bath. See BATHING.

b. A good example of the *acidulo-chalybeate* thermal waters we have in the Springs of Carlsbad. For a full account of the chemical properties of these Springs, see CARLSBAD.

c. The celebrated waters of Aix-la-Chapelle, or Aken, afford a good example of the *fulphureous* thermal waters. See AIX-LA-CHAPELLE.

With respect to the *medicinal properties* of the compound thermal waters, they have all been in much repute as baths, which was, perhaps, the original mode in which the two last varieties in particular were employed. In later times, they have been much used internally. The diseases, says Dr. Saunders, to the cure of which the internal use of Carlsbad waters are applicable, are as various as the nature of their foreign contents; and from the union of several valuable qualities in one water, it may be made use of in cases of very opposite natures, without incurring the censure of employing it indiscriminately as an universal medicine. In common with the other purgative chalybeates, it is found to be eminently serviceable in dyspepsia and other derangements of the healthy action of the stomach, in obstructions of the abdominal viscera, not connected with great organic disease, and in defect or deprivation of the biliary secretion. It is also of use in calculous affections, and is highly esteemed for restoring the uterine system to a healthy state. The same precautions against its internal use in plethoric and irritable habits, and those who are subject to hæmoptysis, or liable to apoplexy, require to be observed here as with any of the other active thermal waters. The Aix-la-Chapelle waters, taken internally, are likewise found essentially serviceable in the numerous symptoms of disorders in the stomach and biliary organs, that follow a life of high indulgence in the luxuries of the table. It also much relieves painful affections of the kidneys and bladder. The same precautions in its use are to be attended to, as those above-mentioned respecting the Carlsbad waters. For the external uses of those waters, see BATHING, and the articles CARLSBAD and AIX-LA-CHAPELLE, before referred to.

Our readers will readily perceive, from the above systematic sketch, that the infinite variety which exists among mineral waters absolutely precludes a *perfect* arrangement of them: we trust, however, that no mineral water can occur which may not be referred to one or other of the above heads or their subdivisions, without any great sacrifice of our principles of arrangement; and, consequently, whose general medicinal properties cannot be estimated with tolerable accuracy *à priori* from its chemical composition.

On the general Uses of Water in a dietetic and medicinal Point of View.—No organic process nor interchange of elements can be supposed to take place without the intervention of a fluid; organized beings, therefore, contain a large proportion of fluid in their composition, through the medium of which that endless series of changes, essential to their existence, is principally effected. The basis of this fluid is universally water, which of all other fluids is the most eminently fitted for dissolving and holding in solution every variety of animal and vegetable matter. See FOOD of Plants.

In animals, the first great step in the series of vital processes is *digestion*; and here nature appears to render the pre-

sence of a fluid particularly necessary, in order, as it were, to insure for herself a sufficiency for her future operations. Accordingly, we find that all animals instinctively take in a certain proportion of fluid, either in the form of simple water, or succulent food. Man alone is the only animal accustomed to swallow unnatural drinks, or to abuse those which are natural; and this is the fruitful source of a great variety of his bodily and mental evils.

We know little of the intimate nature of the digestive process, but we know that it is chiefly effected by means of a highly animalized fluid secreted by the stomach itself. Now this important fluid, by drinking too little or too much, or by other causes, may be rendered too concentrated or too dilute for the due performance of its operations; and dyspepsia, and all its consequences, may thus ensue from habitual errors in the quantity of drink only. The remedy in such cases is obvious, and consists perhaps in nothing more than in duly regulating the quantity of watery aliment, as dictated by instinct, or the sensation of thirst only.

An eminent modern physiologist recommends to abstain from drinking during meals, and for some time afterwards; and as a general rule, this may, perhaps, be proper, since a healthy stomach may be supposed to be always able to secrete fluid enough for its own immediate operations: there can be no doubt, however, but many exceptions to this rule may be met with, arising either from the nature of the food or condition of the stomach, in which moderate dilution is not only grateful but salutary.

With respect to the choice of water as an article of diet, (for our readers will understand that we speak of water only in this place,) those which are hard and impure have long lain under the imputation of producing calculous affections; and we have good authority for stating, that, in many instances, the use of such waters actually increases the painful symptoms of these distressing complaints. It is not perhaps an easy task to explain this, since, with the exception of lime, the substances found in hard waters never enter into the composition of calculi: their operation, therefore, must be rather of a predisposing nature, and is probably exerted upon the organs of digestion, which are well known to be intimately connected with the kidney. A fact which renders this opinion the more probable is, that hard waters are often positively noxious to irritable stomachs, by inducing dyspepsia. In short, pure water, as we formerly observed, must obviously be much better adapted for the important purposes of dilution and solution, than water already saturated as it were with foreign substances; and upon this principle may probably be satisfactorily explained the good effects of Malvern and other waters, whose only characteristic property is, their remarkable degree of purity.

In a medicinal point of view, the use of water as a diluent is most important; and, as Dr. Saunders justly observes, the long list of ptisans, decoctions, &c. usually prescribed by physicians in acute diseases, owe their virtues almost entirely to the watery diluent itself.

The instinctive desires or aversions, continues the same eminent writer, of persons labouring under any species of disordered functions, have been justly considered as deserving the highest attention from the physician, and in most cases will furnish him with useful hints for his treatment of the patient. In acute diseases, the thirst after water is peculiarly remarked as a characteristic symptom, and is a direct instinctive indication of increased heat and want of dilution; and this is so uniform, that the degree of fever may often be pretty well estimated by the eagerness of the sufferer after cold drink. The benefits arising from large dilution in acute diseases, however, are not confined to the mere

mere quenching of thirst, though this is in itself highly advantageous; but it is after so much liquid is added to the circulating mass, that the truly diluent effects are produced. These consist, in Dr. S.'s opinion, in diminishing the morbid heat and violence of reaction in the solids; in preserving all the secretory organs in a pervious state; and in checking that tendency to spontaneous change, which renders the fluids positively noxious to the vessels in which they are contained, and unfit to perform those functions, on which the health of the body so essentially depends.

It appears possible, however, in the opinion of the same author, to carry dilution in active fever to excess. In fever, as is well known, the exhalent vessels are comparatively inactive, or morbidly constricted, and the secretion of urine is defective in quantity. In such cases, it is often better to take liquids in small divided doses, which has the effect of moderating the thirst, without overloading the arterial system, and bringing on that tension and plenitude liable to be produced by swallowing too large a proportion of liquids.

In the use of water in acute diseases, the temperature should be particularly attended to. As a general rule it may be laid down, that the temperature of diluents at the different periods of a cold, hot, and sweating stage of a simple febrile paroxysm, should be hot in the first case, cold in the second, and tepid in the third; and it is chiefly in the second stage that the quantity may be most liberal.

Most of the above remarks are equally applicable to the use of water in chronic diseases in general, but more especially in the deranged functions of the stomach and bowels and biliary organs, occasioned by a long and habitual indulgence in high food, strong drink, and all the luxuries of the table, and which are well known to be so decidedly benefited by the use of water as a medicine. As in acute diseases, so in chronic affections likewise, it is often of great importance to attend to the temperature of the water. A draught of cold water, for example, will often induce sickness and other distressing symptoms in delicate dyspeptic habits, while water rendered slightly tepid may be taken with impunity and even advantage. On the other hand, the habitual use of warm water or drinks is to be avoided, and doubtless always does much harm.

We shall close these remarks by a quotation from Dr. Saunders on the habitual use of water. "Water-drinkers," says this eminent writer, "are in general longer lived, are less subject to decay of the faculties, have better teeth, more regular appetites and less acrid evacuations, than those who indulge in a more stimulating diluent for their common drink."

For the *external* uses of water, see the articles BATH and BATHING, where this part of the subject is treated at length.

On the general Contents of Mineral Waters and their Operation.—The proportions of saline and other ingredients in mineral waters are for the most part so small, as apparently to be insufficient for explaining the effects they often produce upon the animal economy. Many attempts, therefore, have been made to explain this circumstance by different writers, and the subject is so interesting, that we cannot let it pass without making a few remarks upon it.

Dr. Saunders, one of the latest and best writers on mineral waters, very properly ridicules the idea of *specific* and other mysterious properties, by which the older authors attempted to explain their operation. This intelligent physician supposes, that a very great proportion of their effects depends solely upon the diluent operation of the water itself. Of this, as we formerly observed, there can be no doubt, in

many instances; and even in all, the mere bulk and temperature of the water must be allowed to produce a certain proportion of the effects. Still, however, innumerable instances occur, in which these are insufficient to explain the whole, even when aided by the additional circumstance of great dilution, on which the above eminent physician likewise lays great stress. The matter, therefore, has always appeared sufficiently puzzling, and it is only lately that a little light has been thrown upon it by the ingenious views of Dr. Murray, which will be more fully explained in the next section.

There can be no doubt that soluble salts in general are capable of exerting a much more powerful effect upon the animal economy, *ceteris paribus*, than those which are insoluble. The muriates are the most soluble class of salts occurring in waters, and are moreover, independently of this, the most active; at least, this is the case with the earthy muriates, especially the muriate of lime. Now this salt, Dr. M. has rendered it probable, exists in all mineral waters found by the usual analytic method to contain the sulphate of lime and muriate of soda, which comprehend by far the greater number. The same ingenious author has also rendered it probable, that iron not unfrequently exists in the state of muriate instead of carbonate, as commonly believed, as for example, in the Bath waters. With these views in general we perfectly coincide, and have no doubt that, in many instances, a large proportion of the good effects of mineral waters arises from the muriates they contain; but we must confess that many difficulties still appear to us to remain on this obscure subject, which cannot, in the present state of our knowledge, be satisfactorily explained.

Analysis of Mineral Waters.—The analysis of mineral waters has been justly deemed one of the most difficult problems in practical chemistry. This arises partly from the diversified nature of the ingredients, and partly from the minute proportions in which some of them exist. The celebrated Bergman was the first chemist who presented the world with a general method or formula for analysing mineral waters. This was esteemed excellent in its day, and even at the present time may be considered valuable. Twenty years afterwards, Mr. Kirwan published an essay on the subject, which not only comprised all that had been previously done, but contained many valuable additions made by himself. He also proposed a new method of analysis, of which we shall give a short account hereafter.

a. The first step in the examination of a mineral water, is to notice accurately its sensible properties, such as its temperature, colour, transparency, taste, smell, &c.

b. The second step is to ascertain its specific gravity, the spontaneous changes it undergoes on exposure to the air, the application of heat, &c.

c. These preliminary operations being performed, the next object of inquiry, is to endeavour to obtain a knowledge of the different ingredients present by means of *reagents*, or *tests*, as they are usually termed. We have already mentioned the different ingredients commonly met with in mineral waters, and shall now proceed to give a list of the different *tests* by which their presence may be detected. For this list we are chiefly indebted to Dr. Thomson, who has compiled it from Kirwan and others.

1. The *Gaseous Substances* may be separated from water, by boiling it in a retort connected with a pneumatic apparatus, and their nature and proportions may be ascertained in the manner to be presently described.

2. *Hydrogen and its Compounds.*—Sulphuretted hydrogen is readily distinguished by its peculiar smell, by its reddening litmus fugaciously, and by its blackening paper dipped in solution

lution of lead. *Carburetted* hydrogen may be detected by its inflammable nature, and by its yielding carbonic acid by combustion. *Phosphuretted* hydrogen may be known by its peculiar smell and spontaneous inflammability.

3. *Atmospheric Air: Oxygen and Azote*.—The presence of oxygen gas may be known by its power of supporting combustion, and by the diminution which takes place on mixing it with nitrous gas or phosphorus. There is no test for azote, but it is sufficiently characterized by its negative properties.

4. *Alkalies and Alkaline Earths*.—The *alkalies* and *alkaline earths*, as well as their *carbonates*, are distinguished in general by the following tests. Turmeric paper is rendered brown by alkalies, or reddish-brown, if the quantity be minute. Brazil wood is rendered blue not only by the alkalies, but also by the alkaline and earthy carbonates. Litmus paper reddened by vinegar is restored to its original colour by alkalies, and also by the alkaline and earthy carbonates. If these changes are fugacious, we may conclude that the alkali is ammonia. *Fixed* alkalies are indicated when a precipitate is produced by muriate of magnesia after being boiled. The *volatile* alkali, or ammonia, may be readily distinguished by its sensible properties. The *earthy* and *metallic* carbonates are precipitated by boiling the water containing them, except carbonate of *magnesia*, which is only precipitated imperfectly. With respect to the individual substances of this class—*Potash* may be distinguished by the precipitate it produces with the muriate of platina, the sulphate of alumina, and tartaric acid. For *soda* there is no good test, but its salts are easily distinguished from those of potash. *Ammonia* may be known from its odour and other properties above-mentioned. *Lime* is detected by means of the oxalic acid, which occasions a white precipitate. To render its operation certain, however, the mineral acids, if present, must be saturated with an alkali. *Magnesia* and *alumina*. Pure ammonia precipitates both these earths and no other, provided the carbonic acid has been previously separated. Lime-water also precipitates only these two earths, provided the carbonic and sulphuric acids be previously removed. The *alumina* may be separated from the *magnesia* by boiling the precipitate in pure potash, which dissolves the alumina and leaves the magnesia. *Silica* may be ascertained by evaporating a portion of the water to dryness, and redissolving the precipitate in muriatic acid. The *silica* remains behind undissolved.

5. *Metals*.—The presence of *metals* may be suspected, if precipitates are produced by the prussiate of potash and sulphuretted hydrogen. *Iron* may be discovered by the following tests. The addition of tincture of nut-galls gives water containing iron a purple or black colour. If the tincture has no effect upon the water after boiling, though it coloured it before, the iron is in a state of carbonate. Prussiate of potash produces a fine blue precipitate in water containing iron, provided no excess of alkali be present, which must be saturated with an acid. *Manganese* is occasionally present in minute quantity, especially in chalybeate waters. It may be precipitated by ammonia with proper precaution, and is known by the beautiful violet hue it imparts to borax, on being fused with that substance. *Copper* is occasionally met with in waters. It may be detected by the fine blue colour produced on the addition of ammonia; by the red-coloured precipitate produced by the prussiate of potash; or it may be obtained in the *metallic* state by plunging into the water a piece of polished iron. *Lead* is sometimes found in waters that have traversed leaden pipes. Such waters are blackened by a current of sulphuretted hydrogen gas; but to render the presence of the metal

more certain, a portion of the water is to be evaporated to dryness; the remainder is to be tested with nitric acid, and afterwards tested with solutions of the carbonate and sulphate of potash, which produce white precipitates, from which the lead may be readily obtained in the metallic state.

6. *Acids*.—*Carbonic acid*, in a free or uncombined state, may be detected by lime-water, which occasions a precipitate soluble with effervescence in muriatic acid; or by the infusion of litmus, which is reddened, but becomes again blue on exposure to the air. Water containing free carbonic acid loses this property of reddening litmus by boiling. The *sulphuric acid* is readily distinguished by the muriate, nitrate, or acetate of barytes, strontian, and lime, and also by the nitrate or acetate of lead. The most delicate of these tests is the muriate of barytes: this produces a white precipitate, insoluble in muriatic acid. To ensure the operation of this test, it is necessary that no earthy or alkaline combination be present in the water. The *muriatic acid* is detected by the nitrate of silver, which occasions a white curdy precipitate, insoluble in nitric acid. To ensure the operation of this test, the alkaline and earthy carbonates must be previously saturated with nitric acid; and the sulphuric acid, if any be present, must be separated by the nitrate of barytes. *Boracic acid* is detected by means of the acetate of lead. The precipitate formed is insoluble in acetic acid. To render this test certain, the alkalies and earths must previously be saturated with acetic acid, and the sulphuric and muriatic acids removed by means of the acetate of strontian and the acetate of silver.

Such is a brief account of the different tests usually employed to detect the ingredients present in mineral waters, and the most obvious precautions to be observed in their use. It is proper, however, to observe, that there are many circumstances to be attended to, in the use of tests in general, which can only be learnt by personal observation and practice, and that the inexperienced chemist is very liable to be misled by them.

d. Having thus acquired, by the employment of tests, a general knowledge of the ingredients contained in a mineral water, the next object is to endeavour to ascertain the quantities and modes of combination in which they exist; and this constitutes by far the most difficult part of the inquiry.

There are two general modes of conducting the analysis of a mineral water: one is to separate, by various appropriate manipulations, the different ingredients in the same compound forms in which they are supposed to actually exist in the water. The other, recommended particularly by Dr. Murray, is to ascertain, chiefly by means of tests, the quantities of the different *simple* substances, and afterwards to *estimate* from them the quantities of the compounds. The first of these modes, and in some instances a combination of both, is the one which has hitherto been generally adopted by chemists; we shall, therefore, give a short account of the manipulations had recourse to for separating a few of the substances most usually occurring in mineral waters.

1. The gaseous matters are first to be separated in the manner formerly mentioned, and their gross amount ascertained by admeasurement in a jar graduated into cubic inches. Sulphuretted hydrogen, if it be present with other gases, is first to be separated by immersing the jar in warm water, and introducing nitric acid, which absorbs the sulphuretted hydrogen, and the diminution of bulk denotes its quantity.

quantity. If sulphurous acid be present, the above step is unnecessary, for sulphuretted hydrogen never exists in water containing this acid. Sulphurous acid may be separated by introducing into the gaseous mixture a quantity of the peroxyd of lead, in a state of powder. This will gradually absorb the whole, and the diminution of bulk, as before, will denote its quantity. The introduction of a little potash, after this, will absorb the carbonic acid. The remaining gases must be oxygen and azote. The oxygen may be separated by introducing a piece of phosphorus, or by other well-known eudiometrical means; and the azote will remain last of all, unaffected by any of these processes.

2. The earthy carbonates, if any be present, are first to be separated by boiling a given portion of the water for a quarter of an hour. The precipitate thus obtained may consist of a mixture of the carbonates of lime, of magnesia, of iron, and of alumina, and even of the sulphate of lime. Supposing all these to be present, the precipitate is to be treated with dilute muriatic acid, which will dissolve the whole, except the alumina and sulphate of lime. Dry this residuum in a red heat, and note the weight. Then boil it in a solution of carbonate of soda; saturate the soda with muriatic acid, and boil the mixture for half an hour: carbonates of lime and alumina will be precipitated; the lime may be then dissolved by acetic acid, while the alumina will remain; and thus the weight of each may be ascertained.

The muriatic solution contains lime, magnesia, and iron. To separate these, add ammonia, which will precipitate the iron and part of the magnesia. Dry the precipitate, and expose it to the air for some time in a temperature of about 200°. The magnesia may be then separated by acetic acid, and the acetate thus formed is to be added to the muriatic solution. The iron is now to be redissolved in muriatic acid, precipitated by an alkaline carbonate, and dried and weighed.

Muriate of lime and magnesia still remain in solution. To separate them, add sulphuric acid as long as any precipitate appears, then heat the solution, and concentrate. The sulphate of lime thus obtained is to be heated to redness, and its weight ascertained. Lastly, the magnesia may be separated by an alkaline carbonate, or, what is much better, by the phosphate of ammonia.

3. To ascertain the quantity of the alkaline carbonates, supposing them to exist in waters, determine how much of any dilute acid, whose strength has been previously carefully ascertained, is necessary to saturate them; and from this the quantity of alkali can be readily estimated.

4. The alkaline and earthy sulphates may be estimated by the following methods.

The alkaline sulphates may be determined by precipitating their acid by means of the nitrate of barytes, having previously separated all the earthy sulphates.

Sulphate of lime is readily estimated by evaporating the water to a few ounces, the earthy carbonates being previously saturated with nitric acid, and precipitating the sulphate of lime by means of dilute alcohol.

If the sulphate of magnesia or alumina be the only sulphate present, the quantity of either can be readily estimated. If they exist together, the two earths may be precipitated by soda, and afterwards separated by acetic acid in the manner above-mentioned. If sulphate of lime be also present, this may be previously separated in a great degree, as above; or, what is preferable, the lime may be precipitated by an alkali along with the other earths, and afterwards separated. The same holds good also with the sulphate of iron; or the iron may be separated by exposing the water

for some days to the air, and mixing with it a portion of alumina. The oxyd of iron and sulphate of alumina are precipitated together, and may be easily separated, and the quantity of iron ascertained.

5. If muriate of potash or soda exist alone in water, its quantity can be readily estimated by precipitating the muriatic acid with the nitrate of silver. The same process may be followed, if the alkaline carbonates be present; only these carbonates must be previously saturated with sulphuric acid, and, instead of using the nitrate, the sulphate of silver is to be employed.

If the alkaline muriates exist along with more or less of the earthy muriates, or with the muriate of iron, without any other salts, the whole of the earths may be separated by barytes water, and their quantities estimated as before. To discover the proportion of the alkaline muriates, the barytes is to be separated by sulphuric acid, and the muriatic acid expelled by heat. The quantity of the alkaline muriates may be then ascertained by evaporation.

When sulphates and muriates exist together, they may be separated by evaporating the whole to dryness, and dissolving the earthy muriates in alcohol; or, when the water has been duly concentrated, by precipitating the sulphates with the same fluid.

When alkaline and earthy muriates exist with sulphate of lime, this last salt is to be decomposed by means of the muriate of barytes. The estimation is then to be conducted as if nothing but muriates are present, only the proportion of muriatic acid which united in the muriate of barytes, added, must be allowed for.

When muriates of soda, magnesia, and alumina, are present, together with sulphates of lime and magnesia, the water is better examined by two distinct operations. To one portion add carbonate of magnesia, till the whole of the lime and alumina be precipitated. Ascertain the quantity of lime, which gives the proportion of sulphate of lime. Precipitate the sulphuric acid by muriate of barytes: this gives the quantity contained in the sulphate of magnesia and sulphate of lime; and the quantity of sulphate of lime being previously known, that of the sulphate of magnesia can be easily estimated. To a second portion of the water add lime-water, till the whole of the magnesia and alumina be separated. From the weight of these earths the quantity of their muriates may be estimated, that portion of the magnesia previously found to be in union with sulphuric acid being deducted. After this, remove the sulphuric acid by barytes water, and the lime by carbonic acid, and the liquid evaporated to dryness will leave the common salt.

6. Lastly: If the fixed mineral acids should alone be found to exist in a water, it need scarcely be observed that their quantities can be readily ascertained; the sulphuric acid by means of a barytic salt, and the muriatic acid by means of a salt of silver.

All these different precipitates should be dried uniformly, or at least at some known degree of temperature. It is not easy to fix this point, which must in a great degree be regulated by the nature of the salt, and the peculiar views of the analyst; some choosing to reduce the salts to an anhydrous, others to a crystallized state. As a sort of check also to the analysis, it is proper to evaporate a known quantity of the water to dryness, in order to learn the gross amount of the saline matters it contains, which amount is to be compared with the results as obtained by the different processes of the analysis.

Such are a few of the most common methods recommended for separating and ascertaining the proportions of the

different saline substances contained in a mineral water. They must of course be varied according to circumstances; but this, as well as the application of other methods, must depend upon the practical knowledge and judgment of the analyst.

The principles, however, upon which many of the above analytical processes are founded, have been lately called in question by Dr. Murray of Edinburgh, and we think very justly. That gentleman has endeavoured to shew, that we by no means arrive at a just knowledge of the constituents of a mineral water by these processes, and that many of the compounds obtained by them are determined by the processes themselves. The following quotation, from a paper by Dr. Murray, entitled "A general Formula for the Analysis of Mineral Waters," in the eighth volume of the Transactions of the Royal Society of Edinburgh, will convey a distinct idea of his opinions and mode of reasoning upon the subject.

Two methods of analysis have been employed for discovering the composition of mineral waters, what may be called the *direct* method, in which, by evaporation, aided by the subsequent application of solvents, or sometimes by precipitants, certain compound salts are obtained; and what may be called the *indirect* method, in which, by the use of reagents, the principles of these salts, and bases of which they are formed, are discovered, and their quantities estimated, whence the particular salts and their proportions may be inferred.

Chemists have always considered the former of these methods as affording the most certain and essential information. They have not neglected the latter, but they have usually employed it as subordinate to the other. The salts produced by evaporation have been uniformly considered as the real ingredients; and nothing more was required, therefore, it was imagined, for the accuracy of the analysis, than the obtaining them pure, and estimating their quantities with precision. On the contrary, in obtaining the elements merely, no information, it was believed, was gained with regard to the real composition; for it still remained to be determined in what mode they were combined: and this, it was supposed, could be inferred only from the compounds actually obtained. This method, therefore, when employed with a view to estimate quantities, has been had recourse to only to obviate particular difficulties attending the execution of the other, or to give greater accuracy to the proportions, or, at furthest, when the composition is very simple, consulting chiefly of one genus of salts.

Another circumstance contributed to lead to a preference of the *direct* mode of analysis,—the uncertainty attending the determination of the proportions of the elements of the compound salts. This uncertainty was such, that even from the most exact determination of the absolute quantities of the acids and bases existing in a mineral water, it would have been difficult, or nearly impracticable, to assign the precise composition and the real proportions of the compound salts: and hence the necessity of employing the *direct* method of obtaining them.

The present state of the science leads to other views.

If the conclusion was just, that the salts obtained by evaporation, or any analogous process from a mineral water, are its real ingredients, no doubt could remain of the superiority of the *direct* method of analysis, and even of the absolute necessity of employing it. But no illustrations, I believe, are required to prove that this conclusion is not necessarily true. The concentration by the evaporation must, in many cases, change the state of combination; and the salts obtained are hence frequently products of the operation, not

original ingredients. Whether they are so or not, and what the real composition is, are to be determined on other grounds than on their being actually obtained; and no more information is gained, therefore, with regard to that composition, by their being procured, than by their elements being discovered; for when these are known, and their quantities are determined, we can, according to the principle from which the actual modes of combination are inferred, whatever this may be, assign with equal facility the quantities of the binary compounds they form.

The accuracy with which the proportions of the constituent principles of the greater number of the compound salts are now determined, enables us also to do this with as much precision as by obtaining the compounds themselves; and if any error should exist in the estimation of their proportions, the prosecution of these researches could not fail soon to discover it.

The mode of determining the composition of a mineral water, by discovering the acids and bases which it contains, admits in general of greater facility of execution, and more accuracy, than the mode of determining by obtaining insulated the compound salts. Nothing is more difficult than to effect the entire separation of salts by crystallization, aided even by the usual methods of the action of alcohol, either as a solvent or a precipitant, or by the action of water as a solvent at different temperatures: in many cases, it cannot be completely attained, and the analysis must be deficient in accuracy. No such difficulty is attached to the other method. The principles being discovered, and their quantities estimated in general from their precipitation in insoluble compounds, their entire separation is easily effected. Nothing is easier, for example, than to estimate the total quantity of sulphuric acid by precipitation by barytes, or of lime by precipitation with oxalic acid; and this method has one peculiar advantage with regard to accuracy, that if any error is committed in the estimation of any of the principles, it is discovered in the subsequent step of inferring the binary combinations: since, if all the elements do not bear that due proportion to each other, which is necessary to produce the state of neutralization, the excess or deficiency becomes apparent, and of course the error is detected. The *indirect* method, then, has every advantage over the other, both in accuracy and facility of execution.

Another advantage is derived from these views, if they are just, that of precluding the discussion of questions, which otherwise fall to be considered, and which must often be of difficult determination, if they are even capable of being determined. From the state of combination being liable to be influenced by evaporation, or any other analytic operation, by which the salts existing in a mineral water are attempted to be procured, discordant results will often be obtained, according to the methods employed: the proportions at least will be different, and sometimes even products will be found by one method, which are not by another. In a water which is of a complicated composition, this will more peculiarly be the case. The Cheltenham waters, for example, have in different analyses afforded results considerably different: and on the supposition of the salts procured being the real ingredients, this diversity must be ascribed to inaccuracy; and ample room for discussion with regard to this is introduced. In like manner, it has often been a subject of controversy whether sea-water contains sulphate of soda with sulphate of magnesia. All such discussions, however, are superfluous. The salts procured are not necessarily the real ingredients, but in part, at least, are products of the operation; liable, therefore, to be obtained or not, or to be obtained in different proportions, according to the

method employed: and all that can be done with precision is to estimate the elements, and then to exhibit their binary combinations, according to whatever may be the most probable view of the real composition.

The method proposed by Mr. Kirwan, formerly alluded to, consists in determining, chiefly by tests, the quantity of the different saline substances present. But the complicated nature of many of the formulæ, beside the very principle of the method itself, being liable to most of the objections above urged by Dr. Murray against that in common use, render its application difficult, and results uncertain. Upon the whole, therefore, we have no hesitation in saying, that we consider Dr. Murray's views and methods as by far the best, and most likely to lead to correct conclusions, that have yet appeared, and which may be stated in few words, as follows:

“Determine by precipitants the weight of the acids and bases present in a mineral water. Suppose them united in such a manner that they shall form the most soluble salts: these salts will constitute the true saline constituents of the water under examination.”

Dr. Murray illustrates his method of procedure by supposing, as an example, a water found, by the usual tests, to contain the carbonates, sulphates, and muriates of lime, magnesia, and soda. The water is to be reduced by evaporation as far as can be done, without occasioning any sensible precipitation or crystallization. A saturated solution of muriate of barytes is then directed to be added as long as any precipitate falls, and no longer. This precipitates the whole of the sulphuric and carbonic acids, and the carbonate of barytes is to be separated from the sulphate by diluted muriatic acid. Add to the residual liquor a solution of oxalate of ammonia as long as any turbid appearance is produced. By this the whole of the lime is separated. The oxalate of lime is to be calcined, and converted into sulphate of lime, from which the quantity of pure lime may be readily estimated. The next step is to precipitate the magnesia; and for this purpose, Dr. Murray recommends a modification of Dr. Wollaston's process. This consists in adding, first, a solution of neutral carbonate of ammonia, and afterwards a strong solution of phosphoric acid, or phosphate of ammonia; taking care to leave an excess of the carbonate of ammonia. By these processes, the whole of the magnesia is obtained in the state of triple phosphate, and its quantity can be readily estimated. Muriate of soda now remains in solution, and its quantity can be obtained by evaporation. As a check, however, to the different processes, it may be proper to ascertain the quantity of muriatic acid present by means of the nitrate of silver.

If alumina, silica, or iron be present, they are best separated by distinct processes, in the manner formerly described.

Lastly, Dr. Murray recommends that the results of an analysis be stated in three modes: 1st, The quantities of the acids and bases; 2dly, The quantities of the binary compounds, as inferred from the principle that the most soluble compounds are the ingredients; and 3dly, The quantities of the binary compounds, such as they are obtained by the usual modes of analysis. The results will be thus presented in every point of view. As an instance of this method of stating the results of an analysis, we refer our readers to what we have said on *sea-water* in the present article.

Mineral Waters, artificial Preparation of.—Chemistry had no sooner developed the composition of mineral waters, than it suggested methods of preparing them artificially. Accordingly, Bergman and others have given many formulæ for

this purpose, some of which approach the truth, while others are very imperfect. When the composition of a water is very simple, nothing more is required to form it artificially than to know the nature and quantity of the saline substances present, and to dissolve similar quantities of the same saline substances in the same proportion of water. In the earlier periods of chemical investigation, before the nature of gaseous substances was understood, no attempts of course could be made to imitate the important class of waters which derive their chief properties from the presence of such substances; but chemists no sooner became acquainted with the nature of gases, than they began to devise methods of imitating these also; and artificial carbonated waters have been long since prepared as an article of commerce, under the name of *soda water*, superior in point of impregnation to any acidulous waters known. See *Pyrmont*.

It is true that there are some instances of natural chemical solution, which art has not even yet been able to imitate. Of this kind is the solution of silex, which occasionally occurs in mineral waters. It is doubtful, however, if this earth is capable of exerting any salutary effects on the animal economy; and, therefore, we have little occasion perhaps to regret our inability to effect its solution. Another defect in the formation of artificial mineral waters is, that many of the more important ones cannot be obtained in large quantities for bathing, &c. without so great a degree of expence and trouble, as to entirely preclude their use.

On the other hand it seems plausible, in theory at least, that we can improve upon the composition of many mineral waters. Thus, many mineral waters contain ingredients, which, either from the minuteness of the proportion in which they exist, or from their inert nature, may be deemed as superfluous, or in some instances as injurious. Again, others contain their active ingredient in such small quantities, as to require an inconvenient bulk of the water to produce the desired effect: all which defects may be remedied in the artificial preparation, by leaving out the useless or noxious matter, and increasing that in which the proper medicinal virtue resides. Besides these advantages also, we have it in our power to form new and valuable compounds, which are no where to be met with in a natural state.

The first step to the artificial formation of a mineral water is, of course, to know the exact composition of the water we would imitate. Many of the ingredients, however, obtained from mineral waters by the usual modes of analysis, are very little soluble in water: such, for example, are the sulphate and carbonate of lime, &c. which we should attempt in vain to dissolve directly in water. Other modes, therefore, must be devised for this purpose; and Dr. Murray's views of the composition of mineral waters in general will enable us to effect our object, in most instances, very readily and completely, as the following example will shew.

Suppose we wished to imitate the Seltzer water, an English pint of which, according to Bergman's analysis, contains, as before mentioned, of

	Cub. Inches.
Carbonic acid - - - -	17
	Grains.
Carbonate of lime - - -	3
Carbonate of magnesia - -	5
Carbonate of soda - - -	4
Muriate of soda - - - -	17.5
	29.5

WATER.

Of these ingredients, neither the carbonate of lime nor magnesia are soluble in water, nor can be rendered so, without a tedious process of impregnating the water, through which they are diffused, with carbonic acid gas. But if we adopt Dr. Murray's views, and consider a pint of this water as actually containing of

	Cub. Inches.
Carbonic acid gas	17
	—
	Grains.
Muriate of lime -	3.3
Muriate of magnesia	5
Muriate of soda -	7.8
Carbonate of soda	10.3 dry, or 18 crystallized.
	—
	26.4
	—

we can easily imitate its composition in the following manner :

About 35 grains of muriatic acid, of the strength usually met with in the shops, are to be put into a strong bottle, with a pint of water, the acid being introduced to the bottom of the water by a long funnel. Three grains of pure white marble in coarse powder are then to be dropped in, and the bottle closed. When these are dissolved, five grains of the common carbonate of magnesia in powder are to be added ; and after the solution of this, 32 grains of crystallized carbonate of soda, or what is equivalent to this, and preferable, as affording more carbonic acid, 27 grains of bicarbonate of soda, are to be put in. The bottle is to be closed accurately, shaken, and inverted. In a short time a perfect solution takes place, and a liquor is obtained transparent, which sparkles when poured out, has a pleasant taste, and in its composition resembles the Seltzer water.

It might be supposed, says Dr. Murray, that so large a proportion of carbonate of soda could not exist with the muriates of magnesia and lime, without decomposing them ; but on making the experiment, it was found that the above quantities might be dissolved in a pint of water, independently of the excess of carbonic acid, without any apparent decomposition ; the solution remaining transparent, even on exposure to the air.

Upon similar principles may the composition of almost every other mineral water be readily imitated.

We have an agreeable imitation of acidulous waters, under the term of what is called the *effervescent draught*. This consists of two solutions, one of an alkaline carbonate, and the other of the citric or some other vegetable acid, which are directed to be mixed together, and swallowed during the act of effervescence. A more portable form of this grateful draught is to be obtained in the shops, under the name of *Sodaic powders*, *Seidletz powders*, &c. in which the requisite proportions of alkali and acid in their dry state are formed into separate little packets, one of each of which is directed to be dissolved separately in water, and the two solutions to be then mixed, and swallowed during the act of effervescence, as before.

The following, therefore, may be laid down as a general rule for the artificial preparation of mineral waters :—Ascertain, upon Dr. Murray's principles, the precise proportions of the *most soluble* salts that can be present in any given water ; dissolve similar proportions of the same salts in an equal quantity of water, and a compound water will be obtained, precisely similar in its composition to the original.

Catalogue of the most important mineral Waters.—The following catalogue is intended to comprise the principal mineral waters of Great Britain, and some of the more important ones of other countries. Our readers will recollect that, in the preceding article, we divided natural waters into *potable, saline, chalybeate, acidulous, sulphureous*, and *thermal*, and described the general chemical and medicinal properties of each class, as well as of their compounds. To prevent repetition, and to save room, therefore, we have attempted to refer the different springs, mentioned in the following catalogue, to one or other of the above classes : thus, when a spring is stated to be *saline*, its general composition and properties are to be understood to resemble the class of *saline* waters ; and so of the rest.

The moderns have very properly exploded the old notion of the mysterious and *specific* operation of particular springs. But even if this cogent reason for generalization did not exist, it would be impossible, in a work of the present description, to descend to all the minutæ of analysis, &c. supposing them to be known, which is far from being the case : we have thought proper, however, to give a few of the more interesting and instructive recent analyses of some of the most important springs.

Those springs marked thus *, in the following list, are more particularly described in the preceding article, as examples of the different classes.

Abcourt. An acidulous chalybeate spring. See **AB-COURT**.

Aberbrothick, or Arbroath. An acidulous chalybeate spring. See **ABERBROTHICK**.

Acton. A saline spring. See **ACTON**.

Aghaloo, Tyrone, Ireland. A sulphureous spring slightly saline.

* *Aix-la-Chapelle.* Sulphureous thermal springs. See **AIX-LA-CHAPELLE**.

Alford. A saline spring. See **ALFORD**.

Alkerton, near Gloucester. A saline spring.

Anaduff, Leitrim. A weak sulphureous spring slightly saline.

Ashwood, Fermanagh. A sulphureous spring slightly saline.

Asheron, Yorkshire. A strong sulphureous spring slightly saline.

Astrop, Oxfordshire. An acidulous chalybeate spring.

Astwarby, Lincolnshire. A saline chalybeate spring.

Athlone, Westmeath. A chalybeate spring slightly saline.

d'Ax-en-foix, France. Sulphureous thermal springs, in repute as baths.

Baden. Sulphureous springs, formerly in much repute as baths. See **BADEN**.

Bagnigge-Wells. Two springs, one saline, the other chalybeate. See **PANCRA**S.

Baix. Thermal springs, in much repute among the Romans. See **BALÆ**.

Balaruc. Saline thermal springs. See **BALARUC**.

Ballycastle. Two chalybeate springs, one in which the iron is in combination with carbonic acid, the other with sulphuric acid. See **BALLYCASTLE**.

Ballynabinch, Downshire. A sulphureous spring, said to contain iron.

Bagnères, France. Thermal springs, in much repute as baths. See **BAGNERES**.

Balfon, North America. A highly acidulous chalybeate spring. According to the recent analysis of a French chemist, 25 fluid ounces contain of

WATER.

	Cub. Inches.
Carbonic acid - - - -	75
	Grains.
Muriate of soda - - -	31
Carbonate of lime - - -	22
Muriate of magnesia - - -	12.5
Muriate of lime - - -	5
Carbonate of iron - - -	4
	74.5

is about 74°. A wine pint, according to Dr. Carrick's analysis, contains of

	Cub. Inches.
Carbonic acid gas - - -	3.75
Common air - - - -	0.375
	4.125
	Grains.
Muriate of magnesia - - -	0.9
Muriate of soda - - -	0.5
Sulphate of soda - - -	1.4
Sulphate of lime - - -	1.47
Carbonate of lime - - -	1.63
	5.9

Barege. Sulphureous thermal springs, in considerable repute. See BAREGE.

Barnet, Hertfordshire. A weak saline spring. At North-hall, about three miles from Barnet, is another of the same description, but a little stronger.

Bath. Celebrated saline thermal springs, containing likewise a little iron. (See BATH.) One of the most recent and probably correct analyses of these waters is by Mr. Phillips. According to this gentleman, a wine pint contains of

	Cub. Inches.
Carbonic acid - - - -	1.2
	Grains.
Sulphate of lime - - -	9
Muriate of soda - - -	3.3
Sulphate of soda - - -	1.5
Carbonate of lime - - -	0.8
Silex - - - -	0.2
Oxyd of iron - - - -	0.0147
	14.8147

Bilton, Yorkshire. A weak saline sulphureous spring.

Binley, Warwickshire. A saline chalybeate spring.

Borrowdale, Cumberland. A strong saline water. See BORROWDALE.

Borset. Sulphureous thermal springs, in considerable repute. See BORSET.

Brabach, Germany. An acidulous chalybeate spring.

Brandola, Italy. A weak acidulous chalybeate spring.

Brentwood, Essex. A saline spring.

Brighton. A chalybeate spring: sulphate of iron. (See BRIGHTHELMSTON.) According to Dr. Marcet's analysis, a wine pint contains of

	Cub. Inches.
Carbonic acid gas - - -	2.5
	Grains.
Sulphate of iron - - -	1.80
Sulphate of lime - - -	4.09
Muriate of soda - - -	1.53
Muriate of magnesia - - -	0.75
Silex - - - -	0.14
Lofs - - - -	0.19
	8.50

Bristol Hotwells. A simple thermal water. As this spring has not been described in its proper place, we shall insert the following short account of it here. This water is inodorous, perfectly limpid and sparkling, and sends forth air-bubbles when poured into a glass. It is agreeable to the palate, but has no decided taste. Its specific gravity is stated to be 1.00077. Its temperature, upon an average,

It was formerly much celebrated in consumption, but its supposed good effects in this disease have been justly called in question by modern writers.

Bromley, Kent. A chalybeate spring. See BROMLEY.

Broughton, Yorkshire. A strong saline sulphureous spring, similar to that of Harrogate.

Buch, near Carlsbad, in Bohemia. A weak acidulous water.

Buglawton, Cheshire. A saline sulphureous water.

Burlington, or *Briddlington*, Yorkshire. A chalybeate water slightly saline.

Burnley, Lancashire. A chalybeate water slightly saline.

**Buxton*. A simple thermal water. See BUXTON-WATER.

Cannock, Staffordshire. A chalybeate water.

Cargyrle, near Chester. A weak saline water.

Carlsbad. Celebrated acidulo-chalybeate thermal springs. See CARLSBAD.

Carlton, Nottingham. A chalybeate water.

Castleconnel. A chalybeate water. See CASTLECONNEL.

Castlemain. A sulphureous spring said to contain iron. See CASTLEMALIN.

Cawley, Derbyshire. A sulphureous water slightly saline.

Cawthorpe, Lincolnshire. A chalybeate spring slightly saline.

Cheddington, Oxfordshire. A sulphureous water slightly saline.

Chaud Fontaine, near Liege, Germany. Thermal springs celebrated as baths.

**Cheltenham*. Saline and saline chalybeate springs. See CHELTENHAM.

Chippenham, Wiltshire. A chalybeate spring.

Cleves. An acidulous chalybeate spring. See CLEVES.

Clifton, Oxfordshire. A saline spring.

Cobham, Surry. A chalybeate water.

Codsal Wood, Staffordshire. A sulphureous spring.

Colchester, Essex. A saline spring.

Colurian, Cornwall. A chalybeate spring.

Comner, or *Cummer*, Berkshire. A weak saline spring.

Corstorphine, near Edinburgh. A weak sulphureous spring slightly saline.

Coventry. A saline chalybeate spring. See COVENTRY.

Crickle Spa, Lancashire. A strong saline sulphureous water.

Croft, Yorkshire. A sulphureous water slightly saline.

Croft town, Waterford. A sulphureous spring.

Cunley-house, Lancashire. A strong sulphureous spring slightly saline.

Deddington. Saline sulphureous springs. See DEDDINGTON.

Derby. A chalybeate spring.

Derrindaff,

WATER.

Derrindaff, Cavan. A sulphureous spring slightly saline.
Derry-hinch, Fermanagh. A sulphureous spring.
Dog and Duck, St. George's Fields, Southwark. A saline spring.
Drig-well, Cumberland. An acidulous chalybeate spring.
Drumafnave, Leitrim. A strong sulphureous spring slightly saline.

Dublin. Several weak saline springs.
Dulwich, Kent. Pretty strong saline spring.
Dunblane, Perthshire. These springs have been only lately discovered. They have been accurately analysed by Dr. Murray. There are two springs, both of a similar nature, that is to say, saline, with a minute proportion of iron. A wine pint of the *north spring* was found by Dr. M. to contain of

	Grains.
Muriate of soda - - -	24.3
Muriate of lime - - -	18.
Sulphate of lime - - -	3.1
Carbonate of lime with a trace of iron -	0.5
	45.9

The same quantity of the *south spring* yielded

	Grains.
Muriate of soda - - -	22.5
Muriate of lime - - -	16.
Sulphate of lime - - -	2.3
Carbonate of lime - - -	0.3
Oxyd of iron - - -	.15
	41.25

Dunse, Scotland. A chalybeate spring.
Durham. A strong sulphureous water slightly saline.
Egra, Bohemia. A celebrated saline chalybeate spring.
 See EGRA.

Epsom. A celebrated saline spring. See EPSOM.
Felstead, Essex. A chalybeate spring.
Filab, Yorkshire. A saline chalybeate spring.
Francfort on the Maine. Saline sulphureous springs.
 See FRANCFORT.

Galway, Ireland. A chalybeate spring.
Geyser, Iceland. Remarkable thermal springs. See ICELAND.

Glanmille, Ireland. A chalybeate spring.
Glastonbury. A chalybeate spring slightly saline. See GLASTONBURY.

Glendy, Angusshire. A strong chalybeate spring.
Gransbarow, Downshire. A chalybeate spring.
Haigh, Lancashire. A chalybeate spring: sulphate of iron.
Hampstead. A chalybeate water. See HAMPSTEAD. The most recent analysis of this water is by Mr. Blifs, according to whom a wine gallon contains of

	Cub. Inches.
Carbonic acid - - -	10.1
Atmospheric air - - -	90.9
	101.
	Grains.
Oxyd of iron - - -	1.5
Muriate of magnesia - - -	1.75
Sulphate of lime - - -	2.12
Muriate of soda nearly - - -	1.0
Of flex about - - -	.38
	6.75

Hanbridge, Lancashire. A chalybeate water slightly saline.

Hanlys, Shropshire. Two springs, one saline the other chalybeate.

**Harrogate*. Saline sulphureous springs. See HARROGATE.

Hartfell, Annandale. A chalybeate spring: sulphate of iron. According to Dr. Garnett's analysis, a wine pint of this water contains of

	Grains.
Sulphate of iron - - -	10.5
Sulphate of alumina - - -	1.5
Oxyd of iron - - -	1.875
	13.875

Hartlepool. A chalybeate spring. See HARTLEPOOL.

Holt, Wiltshire. A weak saline water.

Holt-nevil, Leicestershire. A chalybeate spring: sulphate of iron. See HOLT Waters.

Jeffop's Well, near Cobham, Surry. A strong saline water slightly chalybeate.

Ilmington, Warwickshire. A chalybeate spring.

Inglewhite, Lancashire. A strong chalybeate spring.

Isle of Wight. A very strong chalybeate: sulphate of iron.

Islington. A chalybeate spring. See ISLINGTON.

Kanturk, Cork. A chalybeate spring.

Katrine Loch, Scotland. On the north side of this lake is a strong chalybeate spring.

Keddleston, Derbyshire. A strong sulphureous water moderately saline.

Kensington. A saline spring. See KENSINGTON.

Kilbreaw, Meath. A chalybeate water: sulphate of iron.

Kilburn, Middlesex. A saline spring.

Kilroot, Antrim. A saline spring.

Kiling-shanvally, Fermanagh. A chalybeate water slightly saline.

Killashber, Fermanagh. A strong sulphureous water.

Kinalton, or *Kynolten*, Nottinghamshire. A weak saline water.

Kincardine. A chalybeate spring.

King's-cliff, Northamptonshire. A chalybeate spring weakly saline.

Kirby or *Kirkby-thower*, Westmoreland. Two chalybeate springs.

Knareborough, the *Dropping-well*, contains lime held in solution by carbonic acid. See KNARESBOROUGH.

Knowsley, Lancashire. A chalybeate spring.

Korytna, Moravia. A very strong sulphureous spring.

Kuka, Bohemia. A chalybeate acidulous water.

Lancaster. A chalybeate spring slightly saline.

Latham, Lancashire. A chalybeate spring.

Leuk, Valois, Switzerland. Thermal springs.

Llandrindod, Radnorshire. Three springs; one saline, another sulphureous, and the third chalybeate.

Llangybi, Carnarvonshire. A saline spring.

Leamington. A saline spring. See WARWICK.

Leez, Essex. A chalybeate spring.

Lincomb, Bath. A chalybeate spring slightly saline.

Lisbeak, Fermanagh. Two sulphureous springs.

Lis-done-varna, Clare. A strong chalybeate water.

Loanbury, Yorkshire. A sulphureous spring slightly saline.

Maccroom, near Cork. A chalybeate spring.

Mahercberg, Kerry. A saline spring.

Mallow,

Mallow, Cork. A pure thermal spring. See MALLOW.
Malton, Yorkshire. A strong chalybeate spring moderately saline.

**Malvern*, Worcestershire. Very pure springs. See MALVERN. One wine gallon of the Malvern Holywell waters, according to Dr. Wilson, contains of

	Grains.
Carbonate of soda	5.33
Carbonate of lime	1.6
Carbonate of magnesia	.919
Carbonate of iron	.625
Sulphate of soda	2.896
Muriate of soda	1.553
Residuum, filix	1.687
	14.610

According to the same chemist, one gallon of the Malvern St. Ann's well contains of

	Grains.
Carbonate of soda	3.55
Carbonate of lime	.352
Carbonate of magnesia	.26
Carbonate of iron	.328
Sulphate of soda	1.48
Muriate of soda	.955
Residuum, filix	.47
	7.395

Markshall, Essex. A chalybeate water.

Matlock, Derbyshire. Thermal springs, temp. about 66°. See MATLOCK.

Maudsley, Lancashire. A sulphureous water moderately saline.

Mechan, Fermanagh. Two sulphureous springs.

Millar's Spa. A chalybeate spring.

**Moffat*, Annandale. Two sulphureous springs. See MOFFAT.

Mossbouse, Lancashire. A chalybeate spring.

Moreton, Shropshire. A saline spring.

Mont d'Or, near Clermont, France. Sulphureous thermal springs.

Mount Pallas, Cavan. A chalybeate spring.

Nevil Holt. See HOLT.

Newnham Regis, Warwickshire. Three chalybeate springs slightly saline.

Newton Dale, Yorkshire. An acidulous water holding lime in solution.

Newton Stewart, Tyrone. A chalybeate spring.

Neuzenice, Germany. An acidulous water.

Nobber, Meath. A chalybeate spring: sulphate of iron.

Normanby, Yorkshire. A sulphureous spring slightly saline.

Nottingham, Dorsetshire. A strong sulphureous water.

Orfson, Nottingham. A chalybeate spring.

Oulton, Norfolk. A weak chalybeate spring.

Oswen Breun, Cavan. A sulphureous spring slightly saline.

Pancras, Middlesex. A saline spring.

Passy, near Paris. A moderately strong chalybeate spring.

Peterhead, Aberdeenshire. A strong chalybeate spring. See PETERHEAD.

Pettygoe, Donegal. A strong sulphureous water, saline.

Pitcaithly, Perthshire. These springs resemble closely those of *Dunblane*, and have been lately analysed by Dr. Murray, according to whom a wine pint contains of

	Cubic Inches.
Atmospheric air	0.5
Carbonic acid gas	1.
	1.5
	Grains.
Muriate of soda	13.4
Muriate of lime	19.5
Sulphate of lime	.9
Carbonate of lime	.5
	34.3

Plombiers, France. A thermal spring.

Pontgibault, France. A weak acidulous spring.

Pyrmont, Westphalia. A highly acidulous chalybeate spring. See PYRMONT.

Queen's Camel, Somersetshire. A sulphureous spring.

Richmond, Surry. A saline spring.

Road, Wiltshire. A chalybeate spring.

Rougham, Lancashire. A saline spring.

St. Bartholomew's Well, Cork. A chalybeate water slightly saline.

St. Bernard's Well, Edinburgh. A sulphureous water slightly saline.

St. Erasmus's Well, Staffordshire. A weak saline water.

St. Winifrid's Well, Flint. A very pure spring. See HOLYWELL.

Scarborough, Yorkshire. A saline chalybeate spring. See SCARBOROUGH.

Schooley's Mountain, United States. A weak chalybeate spring.

Scolliefes, Switzerland. An acidulous chalybeate spring.

**Sea-water*. See SEA and the former part of this article.

**Sedlitz*. A saline water. See SEDLITZ.

**Seltzer*. An highly acidulous water. See SELTZER.

Senec, or *Seend*, Wiltshire. Two chalybeate springs.

**Seydfchutz*, near Sedlitz. A saline water. See SEDLITZ.

Shadwell. A saline chalybeate spring: sulphate of iron?

Shapmoor, Westmoreland. A sulphureous spring slightly saline.

Shettlewood, Derbyshire. A sulphureous spring slightly saline.

Shipton, Yorkshire. A sulphureous spring moderately saline.

Somersham, Huntingdonshire. A chalybeate spring: sulphate of iron. See SOMERSHAM.

**Spa*. Highly acidulous chalybeate springs. See SPA.

Stanger, Cumberland. A saline chalybeate spring.

Stenfield, Lincolnshire. A chalybeate spring slightly saline.

Streatham, Surry. A saline spring. See STREATHAM.

Suchalooza, Germany. An acidulous spring.

Sutton Bog, Oxfordshire. A strong sulphureous spring slightly saline.

Swadlingbar, Cavan. A sulphureous spring.

Swansea, Glamorganshire. A chalybeate spring: sulphate of iron. See SWANSEA.

Sydenham, Kent. A weak saline spring.

Tarleton, Lancashire. A chalybeate spring slightly saline.

Tewksbury, Gloucestershire. A saline spring.

Thetford, Norfolk. A chalybeate spring slightly acidulous.

Thoroton, Nottinghamshire. A chalybeate spring slightly saline.

Thurfsk, Yorkshire. A saline chalybeate spring.

Tibshelf,

WATER.

Tilshelf, Derbyshire. A chalybeate spring slightly acidulous.

Tilbury, Essex. A saline spring slightly chalybeate.

Toberony, near Dublin. A saline spring.

Tonstein, Germany. A saline acidulous spring in considerable repute.

Tralee, Kerry. A chalybeate spring.

**Tunbridge Wells*, Kent. A chalybeate spring. See *TUNBRIDGE WELLS*.

Upminster, Essex. A strong saline sulphureous spring.

Vabls, France. A weak acidulous spring slightly saline.

Vichy, France. A highly acidulo-chalybeate thermal spring. See *VICHY*.

Wardree, Northumberland. A saline sulphureous spring.

Warmbrunn, Silesia. Thermal springs.

Weatherstack, Westmoreland. A saline chalybeate spring.

Wellenbrow, Northamptonshire. A weak chalybeate spring.

West Alkton, Wiltshire. A weak chalybeate spring.

Westwood, Derbyshire. A chalybeate spring: sulphate of iron.

Wexford, Ireland. A weak chalybeate spring.

White Acre, Lancashire. A chalybeate spring.

Wigan, Lancashire. A chalybeate spring.

Wigglesworth, Yorkshire. A sulphureous spring slightly saline.

Wildungan, Germany. A weak acidulous water.

Witham, Essex. A chalybeate spring.

Wirksworth, Derbyshire. A saline sulphureous spring.

Zaborowice, Germany. A weak saline acidulous water.

**Zealand, New*. An acidulous water: muriatic acid.

See the article *AQUÆ*, where many *thermal* and other springs are noticed, which have been omitted in the above catalogue.

Among the older writers on mineral waters, see RUTTY, MONRO, ELLIOT, and others. One of the best modern treatises on mineral waters is doubtless that of Dr. SAUNDERS, to which we have been particularly indebted. Detached essays on particular waters are too numerous to be all noticed. Among the more recent published in this country may be enumerated those of PHILLIPS on the Bath waters; SCUDAMORE on the Tunbridge Wells water; JONES on the Spa waters; and BRANDE on the Cheltenham waters.

The chief of the older writers on the analysis of mineral waters, are BERGMAN and KIRWAN. Latterly, some very valuable essays have been published on this subject by Dr. MURRAY of Edinburgh, of which we have availed ourselves in the above article.

WATER of Crystallization, in *Chemistry*, is a denomination applied to the water attracted by many saline bodies during the act of crystallization. Some salts contain no water of crystallization, while others contain a very large proportion. Water always appears to enter into the composition of crystals in a definite proportion. Water can be commonly separated from salts without affecting their saline properties, and may be restored to them by dissolving them in water, and suffering them to crystallize. See *CRYSTALLIZATION* and *SALTS*.

WATERS, Distilled or Simple, in *Medicine and Pharmacy*, consist chiefly of simple water slightly impregnated with the essential oils of different plants, and are principally used as vehicles for more active remedies. They were formerly very numerous, but their numbers have been very properly much reduced by the moderns. See *AQUÆ Distillatæ*, where all those in common use are enumerated.

WATER, Spirituous, Cordial, or Compound, in *Pharmacy*, &c. was the name formerly given to what are now denominated *Spirits*, the menstruum being alcohol, and the impregnating

ingredients commonly various. See *AQUÆ Cardiacæ*, and *SPIRIT*. For the methods of preparing such compounds, see also *DISTILLATION*, and *OIL, essential*.

WATER, in *Agriculture and Rural Economy*, is a fluid of great utility for many different purposes. The nature of the composition of water, and the great power and capacity which it possesses of taking up and holding a variety of different matters in the state of diffusion or solution, as well as the circumstance of its being every where present amongst almost all kinds of bodies, renders it particularly useful in the growth of plants as crops, and in many other ways. Dr. Woodward, indeed, from finding it to contain the particles of most sorts of extraneous substances, was led to suppose that some of them were the proper matter of nutrition; as water is constantly found to afford so much the less nourishment, the more it is purified by distillation, or other means. So that water, as such merely, did not appear to be the proper nutriment of vegetables, but only the medium or vehicle that contains the nutritious particles or properties, and which conveys them along with it through all the parts of the plant. The more full and complete knowledge of the nature and properties of water which has since been acquired, have, however, set the matter in a more clear and satisfactory point of view. See the article *WATER*.

Water is seldom, if ever, met with in a state of perfect purity, nor often in that even which is sufficiently so for the different operations and uses to which it may be necessary to apply it. Nor have all the trials that have ever been made been yet capable of producing it perhaps perfectly pure. There seems indeed to be no sort of standard by which the weight and purity of water can be readily and easily ascertained. It is, in fact, a very difficult matter, however useful and advantageous it might be in many different intentions, as water scarcely ever continues for any length of time exactly of the same weight, or perhaps purity; as by reason of the air and caloric, or matter of heat contained in it, much variation in respect to the former continually takes place. The effects which different degrees of heat have on the gravity of water are well shewn by the expansion of it in boiling. It is this which makes the chief difficulty in fixing the specific gravity of water, in the view of settling its degree of purity. The purest water that is capable of being obtained is, however, thought by some, as Mr. Hawksbee, who has made many experiments on the subject, to be eight hundred and fifty times heavier than air. But others, whose trials have not been less numerous or correct, have made it not more than about eight hundred, or eight hundred and thirty-six times heavier than air. From whence this general proportion may perhaps be deduced, which may be considered as a sort of standard in the business, that when the barometer is at 30°, and the thermometer at 55°, then water is eight hundred and twenty times heavier than air; and that in such a state the cubic foot of water weighs one thousand ounces avoirdupois, and that of air 1.222, or $\frac{2}{9}$ ths nearly. (See *WATER*.) There is not, however, any very exact standard in air, as the more water there is contained in the air, the heavier it must of course be; for indeed a considerable part of the weight of the atmosphere appears to arise from the water that is contained in it. Consequently, the nearer any water is found to approach the above standards, the purer it may be concluded to be; which may serve to guide and direct many practical uses and applications of the fluid.

In regard to the properties and effects of water, it is well known to be extremely volatile and expansive, being capable of reduction wholly into the state of vapour, and of being dissipated when exposed to heat and unconfined. In this

this state, when properly confined, it is of great use and application for a variety of purposes. See STEAM.

It is found, however, that water, when heated in an open vessel, acquires no more than a certain determinate proportion or degree of heat, whatsoever may be the intensity or the length of continuance of the fire to which it is exposed; which greatest proportion or degree of it is when it boils in the completest manner. The degree of heat, however, which is necessary to make water boil perfectly, is variable, according as the purity of the water, and the weight of the atmosphere, may happen to be. A knowledge of this may be of considerable utility and benefit in the application of heat to this fluid, in a number of operations, as tending to save time, trouble, and the consumption of fuel.

The ready penetrability and separability of water from the bodies with which it may have united, as well as its properties and powers of cohesion, solution, and coagulation, render it still more extensively applicable and useful on many occasions.

Water is a fluid which, in popular language, is distinguished into many different kinds, according to the qualities of it, and the circumstances under which it makes its appearance, or is found (see the preceding article WATER); as *fresh* water, or that which is perfectly insipid, without any saline or other taste, and inodorous, being that which is the natural and pure state of water: in this state, it is well fitted for most sorts of domestic as well as many other uses: *hard* water, or that in which soap does not completely or uniformly dissolve and diffuse itself, but appears in a sort of curdled or coagulated state: it is certain from this that the dissolving power of hard water is less than that of soft; and that hence it is less fit for washing, bleaching, dyeing, boiling culinary vegetables, watering plants and trees, and many other purposes. It is, for the most part, found, that the hardness of water proceeds either from saline matters, or from the presence of gas. The hardness which arises from saline matters may mostly be discovered and removed by the addition of small quantities, as a few drops, of a solution of fixed alkali; and that which is caused by the latter by-boiling, or exposure to the open air for some length of time. That the waters of springs are hard; but those of rivers soft. That hard waters are remarkably indisposed to corrupt; they even preserve putrescible substances for a considerable length of time; hence they would seem to be best fitted for keeping, especially as they are so easily capable of being softened by a very little of the alkaline solution being added to them. *Putrid* water is that which has acquired an offensive smell and taste by the putrescence of the animal or vegetable substances which are contained in it. This sort of water is of a very pernicious quality, and quite unfit for any purpose. Caustic lime, when put into water, is useful in preserving it longer in a sweet state; and even exposure to the air in broad shallow vessels has the same effect. And water in this putrid state may be, in a great measure, rendered sweet by having a current of fresh air passed through it, from the bottom to the top. Water in this condition is, of course, always to be avoided, except for the purpose of manure, for which, in some cases, it is of great use. *Rain-water*, or that which may be considered as a pure sort of distilled water, but as impregnated during its passage through the air with a considerable quantity of putrescent matter, whence, in some measure, its great superiority to any other in fertilizing the earth or soil, as well as in promoting the growth of trees and plants. Whence too its inferiority for some domestic purposes to that of the spring or river kind, even where it can be readily and well procured; but,

more especially, such as is collected and gotten from spouts, trunks, and other contrivances put below the roofs of houses and other buildings, which are the usual modes of procuring it in this country, which is obviously very impure, and in a short time becomes in the putrid state. From its softness, it, however, answers well in some uses, after it has become pretty pure by standing. *River-water*, or that which is next in purity to that of snow, or the distilled kind, and which, for most domestic and some other uses, is superior to either of them, as having less putrescent matter, and more fixed air, or carbonic acid gas in it. Of this water, that, however, which runs over a clean, rocky, stony, or gravelly bottom, is by much the purest. *River-waters*, in general, are found to putrefy sooner than those of springs; and that during their putrefaction they throw off a part of the extraneous matter they contain, and at length become sweet again, and purer than in their first state; after which they will commonly preserve sweet a great length of time; this is particularly the case with some river-water, as that of the Thames. It is this sort of water that is so extensively useful in improving grass-lands, when thrown over them in a proper manner. See WATERING Land, and WATER Meadow.

There are some other sorts of water, as *salt* water, or that which contains large portions of salt in it, so as to be sensible to the taste. This is of most use in the preparation of that substance from it, but may perhaps be applicable in some other ways. *Sea-water*, or that which is a sort of an assemblage of bodies or substances, in which this fluid may be said to have barely the principal part: it is, in short, an universal collection of most of the matters in nature, sustained and kept swimming in this fluid as a medium or vehicle: being a diffuse solution of various substances, as common salt, bitter cathartic salt, different other saline matters, and a compound of muriatic acid with magnesia, mixed and blended together in a variety of proportions. It is capable of being freshened by simple distillation, without any addition; and is about three parts in a hundred heavier than common water; the temperature of it at great depths being from thirty to forty degrees; but near the surface it follows the temperature of the air more nearly. It is probable, from some trials lately made with it, that it may be useful when applied to land in some cases. Its greater weight and other properties would seem to be favourable for this in some intentions. It is the muddy material conveyed in the state of diffusion in this water, which is found so beneficial in the warping of land in some cases and situations. (See WARPING of Land.) *Snow-water*, or that which is the purest of all the common waters, when the snow has been collected in its pure state, and kept in a dry place, in clean glass vessels, not closely stopped, but covered from dust and other such matters; this water becomes in time putrid, although in well-stopped bottles it will continue unaltered for several years; but distilled water undergoes no alteration in either circumstance. Snow-water will be seen below to be useful in promoting the nutrition of plants. *Spring-water*, or that which is commonly impregnated with some sorts of materials or other, as a small portion of imperfect neutral salt extracted and taken up from the different strata through which it passes and percolates; great quantities of stony matter, which are deposited as it runs along, and large masses of stone thus formed, sometimes too incrustating different substances of the animal and vegetable kinds, which it is said to petrify. Spring-water is much used for domestic purposes in many cases, and on account of its coolness and clearness forms a suitable drink for man and animals; but from its being usually somewhat hard, is inferior in some intentions to that which has run a considerable distance

in an open channel, exposed to the action and influence of the air.

The water of springs arises and is caused by rain, and from mists and moisture in the atmosphere; which falling upon the hills and higher grounds, as well as other parts, soak in and sink down into the earth, passing along between the different strata, until they find a vent or outlet in the form of a spring. See *DRAINING of Land*, *SPRING*, and *WALL*. Also *SPRING-Draining*.

It is only under certain circumstances that spring-water can be applied over the surface of grass-land with much benefit; as where it is considerably impregnated and loaded with particular sorts of materials, as those of the calcareous, and perhaps some other kinds.

A late philosophical writer has remarked, that the necessity of much water in the progress of the growth of plants or their vegetation, is shewn by the great quantity which exists naturally in all parts of them; inasmuch that many roots, as those of the squill and rhubarb, are known to lose about six parts out of seven of their original weight, simply by drying them before the fire; which quantity of moisture nevertheless does not exhale in the common heat of the atmosphere during the life of the root; as may be seen in the growth of squills in the shop of the druggist, and of onions on the floors of the store-rooms of the seedsmen. And that a second necessity of much water in the economy of their vegetation or growth may be deduced from the great perspiration of them, which appears from the experiments of Hales and others, who, like Sanctorius, have, it is said, estimated the quantity of perspiration from their daily loss of weight; which, however, it is suggested, is not an accurate conclusion, either in respect to plants or animals, as they both absorb moisture from the atmosphere, as well as perspire it. But that this great perspiration of vegetables, like that from the skin and lungs of animals, does not appear to consist of excrementitious matter, because it has in general no putrescent smell or taste, but seems to be secreted first for the purpose of keeping the external surface of the leaves from becoming dry, which would prevent the oxygen of the atmosphere from entering into the vegetable blood or juice through them; since, according to the experiments of Dr. Priestley on animal membranes, the oxygen will only pass through them when they are moist. A second use of this great perspiration is, it is said, to keep the bark supple by its moisture, and thus to prevent its being cracked by the motion of the branches in the wind. And though a great part of this perspirable matter is probably absorbed, as on the skins of animals, yet as it exists on so large a surface of leaves and twigs, much of it must necessarily evaporate on dry and windy days.

And the discovery of the decomposition of water has, it is said, led to a third great use of water in the vegetable economy, which is probably owing to its ready decomposition by their organs of digestion, sanguification, or juice-forming, and secretion. This is evinced, it is thought, first, by the great quantity of hydrogen which exists in the composition of many of their inflammable parts; and secondly, from the curious circumstance which was first discovered by the ingenious Dr. Priestley, that the water which they perspire is hyper-oxygenated, and in consequence always ready to part with its superabundance of oxygen, when exposed to the sun's light; whence it may be concluded, it is thought, that a part of the hydrogen, which was previously an ingredient of this water, has been separated from it, and used in the vegetable economy. And that, from the decomposition of water, when confined in contact with air beneath the soil, the nitrous acid seems to be produced, and

ammonia, both of which are believed to be useful to vegetation and the growth of plants.

But that, beside these peculiar uses of a great quantity of water, the more common uses of it both to vegetable and animal life, along with caloric or the matter of heat, are to produce or preserve a due suppleness or lubricity of the solids, and a due degree of fluidity of liquids which they contain or circulate; and, lastly, for the purpose of dissolving or diffusing in it other solid or fluid substances, and thus rendering them capable of absorption, circulation, and secretion.

It is beneficial, too, in the view of promoting the fertility of grass-lands, by the occasional suffusion or flowing it over them, by which it not only supplies simple moisture for the purposes above noticed in the drier parts of the season, but brings along with it calcareous earth and azotic air from the neighbouring springs in many instances, or other manures from the rivers and brooks. Still another beneficial consequence of it is to give a due penetrability to the soil or mould, which otherwise, in most situations, becomes so stiff and hard, as to stop the elongation and distension of the tender roots of plants; but nevertheless, the cohesion of the soil or earthy particles may be too much or too greatly diminished or lessened, by great and perpetual moisture, so as not to give sufficient firmness to the roots of trees or plants. It may also be injurious in some cases, as in very hasty showers, by washing off and taking away much of the decomposing animal and vegetable recrement, which are soluble or diffusible in it, and carrying them down the rivers and brooks into the sea; and from the sides of hills, injury in this way is produced by small showers; and the evaporation of water or moisture from the surface of the earth may produce so much cold as to injure such terrestrial plants as are too long covered with it.

The author of the "Elements of Agricultural Chemistry" has concluded, that water is absolutely necessary to the economy of vegetation, both in its elastic and fluid state; and that it is not devoid of use, even in its solid form. Snow and ice are, it is said, bad conductors of heat; and that, consequently, when the ground is covered with snow, or the surface of the soil or of water is frozen, the roots or bulbs of the plants beneath are protected by the congealed water from the influence of the atmosphere, the temperature of which, in northern winters, is usually very much below the freezing-point; and this water becomes the first nourishment of the plants in early spring. The expansion of water too during its congelation, at which time its volume increases one-twelfth, and its contraction of bulk during a thaw, tend, it is observed, to pulverize the soil, to separate the parts of it from each other, and to make it more permeable to the influence of the air, and the fibres of the roots of vegetables.

Water also, as constituting the daily necessary drink of the different sorts of domestic animals which form the livestock of the farmer, is always to be particularly attended to, and to be provided as fully and of as good quality as can possibly be met with; as such stock constantly do best where they have plenty of water. See *POND*, and *LIVE-Stock*.

Application of water, whether of ponds, brooks, rivers, or other kinds, to the purpose of fisheries, is likewise a matter of great individual utility and benefit, as well as general national advantage. It is the means of increasing a most useful sort of food in almost an unlimited manner, at very little cost or expence. It provides much profitable labour and employment to some of the working classes of society; and from the trifling charge incurred in providing it,

and the readinefs of its difpofal, muft be a fource of great wealth to the country. It fhould, of courfe, be encouraged as much as poffible, wherever it can be done with convenience and fuccefs, in all parts of the kingdom. See *FISH-Pond*, *POND-Fifberies*, and *SALMON-Fifberies*.

WATER, *Afcend of*, in *Hydraulics*. See *ASCENT* and *CAPILLARY Tubes*.

WATER, *Highb and Low*. See *FLUX*, *HIGH*, and *TIDE*.

WATER, *Motion of*. The theory of the motion of running water is one of the principal objects of hydraulics, and many eminent mathematicians have applied themfelves to this fubject. But it were to be wifhed that their theories were more confiftent with each other, and with experience. The curious may confult fir Ifaac Newton's *Principles*, lib. ii. prop. 36. with the comment. Dan. Bernouilli's *Hydrodynamica*. Jo. Bernouilli, *Hydraulica*, Oper. tom. iv. p. 389, feq. Dr. Jurin, in the *Phil. Tranf.* N^o 452, and in Dr. Martyn's *Abridg.* vol. viii. p. 282, feq. S'Gravafande, *Phyfic. Elem. Mathemat.* lib. iii. par. ii. Polenus, de *Caftellis*, and others.

Mr. Maclaurin, in his *Fluxions*, art. 537. feq., has illuftrated fir Ifaac Newton's doctrine on this intricate fubject, which ftill, notwithstanding the labours of all thefe eminent authors, remains in a great meafure obfcure and uncertain. Even the fimple cafe of the motion of running water, which is when it iffues from a hole in the bottom of a vefel kept constantly full, has never yet been determined, fo as to give univerfal fatisfaction to the learned. We fhall here mention fome of the phenomena of this motion, as ftated by Dr. Jurin from Poleni; referring for other obfervations on this fubject to *FLUIDS*, and *Hydraulic Laws of FLUIDS*.

1. The depth of the water in the vefel, and the time of flowing out being given, the meafure of the effluent water is nearly in proportion to the hole.

2. The depth of the water, and the hole being given, the meafure of the effluent water is in proportion to the time.

3. The time of flowing out, and the hole being given, the meafure of the effluent water is nearly in a fubduplicate proportion to the height of the water.

4. The meafure of the effluent water is nearly in a ratio compounded of the proportion of the hole, the proportion of the time, and a fubduplicate proportion of the depth of the water.

5. The meafure of the water flowing out in a given time, is much lefs than that which is commonly affigned by mathematical theorems. For the velocity of effluent water is commonly fuppofed to be that which a heavy body would acquire *in vacuo* in falling from the whole height of the water above the hole; and this being fuppofed, if we call the area of the hole *F*, the height of the water above the hole *A*, the velocity which a heavy body acquires in falling *in vacuo* from that height *V*, and the time of falling *T*; and if the water flows out with this conftant velocity *V*, in the time *T*, then the length of the column of water, which flows out in that time, will be $2 A$, and the meafure of it will be $2 A F$. But if we calculate from Poleni's accurate experiments, we fhall find the quantity of water which flows out in that time to be no more than about $\frac{5}{7} \frac{2 A F}{T}$ of this meafure $2 A F$. Polen. de *Caftellis*, art. 35. 38. 39. 42. 43.

Poleni alfo found, that the quantity of water flowing out of a vefel through a cylindrical tube far exceeded that which flowed through a circular hole made in a thin lamina, the tube and hole being of equal diameter, and the height of the water above both being alfo equal; and he found it to be fo when the tube was inferted, not into the bottom, which others had obferved before, but into the fide of the vefel.

6. Since the meafure of the water running out in the time *T*, is $2 A F \times \frac{5}{7} \frac{2}{T}$, the length of the column of water, which runs out in that time, is $2 A \times \frac{5}{7} \frac{2}{T}$. Therefore if each of the particles of water, which are in the hole in the fame fpace of time, paffes with equal velocity, it is plain that the common velocity of them all is that with which the fpace $2 A \times \frac{5}{7} \frac{2}{T}$ would be gone over in the time *T*, or the velocity $V \times \frac{5}{7} \frac{1}{T}$. But this is the velocity with which water could fpring *in vacuo* to near $\frac{1}{3}$ of the height of the water above the hole.

7. But when the motion of water is turned upwards, as in fountains, thefe are feen to rife almoft to the entire height of the water in the ciftern. Therefore the water, or at leaft fome portion of the water, fpouts from the hole with almoft the whole velocity *V*, and certainly with a much greater velocity than $V \times \frac{5}{7} \frac{1}{T}$.

8. Hence it is evident, that the particles of water, which are in the hole in the fame point of time, do not all burft out with the fame velocity, or have no common velocity; though fome mathematicians have hitherto taken the contrary to be certain.

9. At a fmall diftance from the hole, the diameter of the vein of water is much lefs than that of the hole. For inftance, if the diameter of the hole be 1, the diameter of the vein of water will be $\frac{2}{7}$, or 0.84, according to fir Ifaac Newton's meafure, who firft obferved this phenomenon;

and according to Poleni's meafure $\frac{20}{26}$, or $\frac{20\frac{1}{2}}{26}$, that is, taking the mean diameter 0.78, nearly.

As to the manner of accounting for thefe phenomena, we have already obferved that authors are not agreed; and it would be far beyond our defign to ftate their different theories, we muft therefore refer to the originals above quoted.

Neither are authors agreed as to the force with which a vein of water, fpouting from a round hole in the fide of a vefel, preffes upon a plane directly oppofed to the motion of the vein. Moft authors agree that the preffure of this vein, flowing uniformly, is equal to the weight of a cylinder of water, the bafis of which is the hole through which the water flows, and the height of which is equal to the height of the water in the vefel above the hole. The experiments made by Mariotte, and others, feem to countenance this opinion. But Mr. Daniel Bernouilli rejects it, and eftimates this preffure by the weight of a cylinder, the diameter of which is equal to the contracted vein (according to fir Ifaac Newton's obfervation above-mentioned), and the height of which is equal to twice the height of the water above the hole, or, more accurately, to twice the altitude correfponding to the real velocity of the fpouting water; and this preffure is alfo equal to the force of repulfion, arifing from the reaction of the fpouting water upon the vefel. For he fays that he can demonftrate, that this force of repulfion is equal to a preffure exerted by a vein of fpouting water upon a plane directly oppofed to its motion, if the whole vein of water ftrikes perpendicularly againft the plane. From whence it would follow, that the preffure or force of the vein will be greater in proportion, as its contraction is lefs; and this contraction vanifhing, as it does when the water fpouts through a fhort tube, and the vein being at the fame time fuppofed to have the whole velocity it can acquire by theory, the fpouting water will then exert a preffure double to what is commonly fuppofed. But the actual velocity of the water being always fomething lefs than it ought to be by theory, and the vein of water being not uncommonly contracted to almoft one half, experi-

periments have led authors to think, that the pressure, exerted by spouting water, was equal to the weight of a cylinder of the same diameter with the vein, and of the height of the water above the hole. The ingenious author remarks that he speaks only of single veins of water, the whole of which are received by the planes upon which they press; for as to the pressures exerted by fluids surrounding the bodies they press upon, as the wind, or a river, the case is different, though confounded with the former by writers on this subject. *Hydrodynamica*, sect. 13. p. 289.

M. Bernouilli endeavours to confirm his theory by a dissertation in the eighth volume of the *Acta Petropolitana*; where he observes, that the experiments formerly made before the Academy of Sciences at Paris, to establish the quantity of the pressure exerted by a vein of spouting water, are very far from proving the truth of the rule they are brought to establish. For instance, in one of those experiments, the height of the water in the vessel above the hole from whence the vein spouted was two feet Paris measure; the diameter of the circular hole, which was cut in the horizontal bottom of the vessel, was four lines; and the force of the vein of water was observed to be one ounce and three-quarters. But the weight of a cylinder of water of the diameter of the hole, and of the height of the water in the vessel, is scarce equal to one ounce and three-eighths. The difference, therefore, is at least three-eighths of an ounce, which is about three-elevenths of the whole weight of the before-mentioned cylinder of water. So that it is surprising, that this difference should have been ascribed to the removal of the plane, receiving the impulse, to some distance from the hole; for this cause, supposing the plane removed to the distance of two inches, could not produce an increase of one-sixteenth of an ounce. It appears, therefore, that the common opinion is rather overturned than confirmed by experience. *Du-Hamel*, *Hist. Acad. Paris*, ann. 1679, sect. 3. cap. 5.

M. Bernouilli, on the other hand, thinks his own theory sufficiently established by the experiments he relates; for the particulars of which, we refer to the *Acta Petropolitana*, vol. cit. p. 122, seq.

This ingenious author thinks that his theory of the quantity of the force of repulsion, exerted by a vein of spouting water, might be usefully applied to move ships by pumping; and he thinks the motion produced by this repulsive force would fall little, if at all, short of that produced by rowing. He has given his reasons and computations at length in his *Hydrodynamica*, p. 293 to 302.

The science of the pressures exerted by water, or other fluids in motion, is what M. Bernouilli calls *hydraulico-statica*. This science differs from hydrostatics, which considers only the pressure of water and other fluids at rest; but hydraulico-statics considers the pressure of water in motion. Thus the pressure exerted by water, moving through pipes, upon the sides of those pipes, is an hydraulico-statical consideration, and has been erroneously determined by many, who have given no other rules in these cases, but such as are applicable only to the pressure of fluids at rest. See *Hydrodynam.* sect. 12. p. 256. seq.

WATER, Raising of. Machines for this purpose are so numerous, that a minute description of such hydraulic machines as are in common use would fill a volume; and a scientific account of their principles, with the maxims necessary to be observed in their construction, would form a very complete body of mechanical science: this is far beyond the limits of an article like the present, in which we can only introduce the most striking machines which

have not already been explained in different articles of this work; and for others, we must refer to the original works in which they are described.

The most complete collection of hydraulic machines is that of Jacob Leopold, entitled "*Theatrum Machinarum Hydraulicarum*," published at Leipzig, in 1724 and 1725, in 2 vols. folio; these form part of his voluminous "*Theatrum Machinarum*," which may be considered as containing all that was known in mechanics at that period.

M. Belidor, in his "*Architecture Hydraulique*," 1737, has described many machines which were invented since the date of Leopold's work. This eminent engineer was a good mathematician, and his work may be considered as a standard for the theory of the hydraulic machines of which it treats. The "*Experimental Philosophy*" of Defaguliers contains some chapters on hydraulic machinery, in which he generally follows Belidor very closely, but has translated the mathematical investigations of the former into the ordinary processes of arithmetic, to adapt them to the comprehension of mechanics; and in this point of view, the works of Defaguliers have been of great use. On the other hand, M. Prony published a modern edition of Belidor's work in 1790, in which, in most cases, he has transferred the processes of the original into the modern modes of analysis; but on the whole, he has added little to our real knowledge, except his descriptions and superb plates of Mr. Watt's steam-engine.

We do not recollect any complete collection of machines for raising water since Belidor, although the inventions of the last century are both numerous and important. Much information relative to them may be derived from Gregory's "*Mechanics*," in 2 vols. 8vo.; Dr. Robison's *Works*, and his excellent articles *Hydrodynamics*, *Pump*, and *Waterworks*, in the *Encyclopædia Britannica*; and from various miscellaneous publications, such as the *Repertory of Arts*, and the *Transactions of different learned Societies*; also the collection of Mr. Smeaton's *Reports*, in 3 vols. 4to. It is much to be regretted, that this excellent engineer never completed a design which he formed, to publish a complete collection of practical hydraulic machines founded on his own experience. Among his manuscript papers which have been lent to us by sir Joseph Banks, we find an outline for this work, of which we have availed ourselves in this article.

In considering machines for raising water, they may be classed under two heads:

First, those machines which actuate some kind of bucket or vessel adapted to contain water, which vessel is raised up when full of water, and discharges its contents into an elevated reservoir, then descends empty in order to repeat its action: of this species are, the buckets for wells, scoops, Persian and Chinese wheels, chaplets or chains of buckets, the Noira, and the screw of Archimedes. It is evident from the nature of all this class, that they are incapable of raising water to a greater height than that to which the machine is elevated, or provided with the means of drawing up the buckets or other vessels; and further, that they cannot raise constant streams of water, but that the water must be given out by a succession of discharges from the different buckets or vessels.

The second class comprises those machines which act by means of valves and pistons moving in cylinders, or other equivalent contrivances, and force the water to ascend through pipes or tubes: these machines have the advantage of raising the water to very great heights above the place where the machine is placed. The greater part of these machines we have already described under the article **PUMP**,

and there remain but few to be considered in the present article; viz. the varieties of the hydraulic ram, of the Chrennitz fountain, and of the fyphon machines.

The most obvious means of raising water is by the operation called baling, that is, lifting up water in a bucket, or other vessel, by the force of a man's arm. This method is extremely fatiguing, and is only adapted to very small elevations, such as clearing the water from a boat, &c. The most ancient hydraulic machine acts on this principle, such as the scoop and troughs, the Fen wheel, Persian wheel, the Noira, &c.: it is, therefore, with these machines we shall commence.

The *Dutch water-scoop*, or shovel, is the best means of baling out water. The scoop is a kind of box, made of five pieces of board, with one end and one side open: this box is fixed at the extremity of a long pole, which the workman holds in his hand, and the weight of the scoop is borne by a cord tied to the pole near to the box, and suspended from a tripod, formed of three poles tied together at the top. The man works the machine by swinging the scoop backwards and forwards in the direction of the length of the pole; in moving the box forwards, he depresses the end of the pole, which causes the box to dip into the water, and take up a quantity which it will throw forwards and rather upwards to a considerable distance. In bringing the scoop back for another stroke, he depresses the end of the pole which he holds in his hand, and thus keeps the box out of the water. Of course this method is only applicable where the height to which the water is to be raised, or rather thrown, is very small. M. Belidor informs us, that a workman can only remove half a cubic foot in two vibrations, which he will perform in four seconds; this is at the rate of $7\frac{1}{2}$ cubic feet *per* minute, or 450 cubic feet *per* hour: it is rarely applicable, except to throw the water over a bank which forms the boundary of a ditch, or other place of small depth, which is to be emptied.

The *laving gun*, which is used in salt-works from its simplicity, comes next. It is a trough of five or six feet in length, made small at one end like a spout, and gradually increasing to the opposite end, where it is about a foot or eighteen inches square. The small end is supported on pivots upon the bank over which the water is to be raised, and a lever is applied to it for a man to work it by. The large end of the trough will dip into the water, when it descends and becomes filled; but when lifted the least above the horizontal position, the contained water will run along the trough, and be delivered over the bank through the spout. This machine is much improved by making it double, or with two troughs, on the opposite sides of the centre; thus when one ascends, the other will descend so as to raise up a constant stream, which it must, in this case, deliver at a spout sideways, near to the pivot or centre on which it plays. This double machine will raise a copious stream of water, but is confined to small heights of three or four feet. If the large end of the trough has a valve opening into it to admit the water, it will fill itself more readily. A machine which operates on the same principle as this, is called the scoop-wheel, or tympanum, which is in fact several double laving machines arranged round the centre like a wheel. The advantage of this wheel is, that it always moves in the same direction, whereas the simple machine requires a reciprocating motion.

The *tympanum*, or *scoop-wheel*, mentioned by Vitruvius, is a great hollow wheel formed by a kind of barrel or drum (as its name imports): it is composed of several planks joined together, well caulked and pitched, and having a ho-

izontal axle with pivots at the ends, on which it turns. The interior capacity of this drum is divided into eight equal spaces, by as many partitions placed in the directions of the radii; each space or cell has an orifice of about six inches in width in the rim of the drum or wheel. These openings are so shaped, as to facilitate the admission of the water; moreover, there are eight hollow channels running along the axle of the wheel and contiguous to each other, each corresponding to one of the eight large cells; into these channels the water passes out of the cells just mentioned, and after running along the channels in the axis of the wheel to a convenient distance, it escapes through orifices into a reservoir placed just under the axle. Thus when the wheel is turned round, the water is elevated through a vertical height equal to the radius of the hollow wheel.

When the tympanum is used to raise water from a running stream, it is moved by means of float-boards fixed on the circumference, which are impelled by the stream; but when it is employed to raise stagnant waters, there is commonly a smaller hollow wheel fixed on the shaft at the side of the tympanum, which is turned by men walking in it, as in the old walking-crane. The chief defect of this machine is, that it raises the water in the most disadvantageous situation possible, for the load of water is always towards the extremity of a radius of the wheel, and the length of the effective lever which answers to it must continually increase as the water is raised through the whole quadrant, which the water describes in passing from the bottom of the wheel to the altitude of its centre, so that the power must act in the same manner as if it were applied to a winch or crank handle, and cannot act uniformly.

The *horn-wheel* was contrived to remedy this defect: it is so called, because the segments which pass from the circumferences of the large flat cylinder to its centre are not straight radii, as in the former instance, but are curved spirally. The scoops, or mouths, by turns, dip into the water, and as they rise up cause the water to pass up the horn, or curved segment, until it is as high as the centre of the wheel, and then it is discharged into a trough placed under the end of the axis, which is hollow, and has its pivots fastened to a cross.

M. de la Faye has investigated the proper curves for the scoop segments of this machine in the following manner:—When we evolve the circumference of a circle by unwrapping a string from the circumference, the end of the string will describe a curve called the involute of the circle, of which all the radii are so many tangents to the circle, as is shewn by the string in its different positions whilst tracing the curve, and likewise all the radii are respectively perpendicular to the several points of the curve described by the end of the string.

The greatest radius of this curve is a line equal to the periphery of the circle evolved. The truth of this statement is shewn by geometricians, when treating of the generation of *Evolute* and *Involute Curves*. See those articles.

Hence, having an axle, whose circumference a little exceeds the height to which the water is proposed to be elevated, let the circumference of the axle be evolved, and it will make a curve which will be the involute of the circle, as before mentioned. Now, let a number of pipes, or trunks, be made exactly with this curvature, and then put together around the axle, in form of a wheel, so that the further extremities of these canals will successively enter the water that is to be elevated, whilst the other extremities abut upon the shaft which is turned. Then, in the course of the rotation of the wheel, the water taken in at the extremity of each canal will rise in a vertical line, which is a tangent to

WATER.

to the shaft, because the curves of the several channels will be at right angles to this vertical line, in the points where the line intersects the curves; and this is true in whatever position the wheel may be. Thus the action of the weight continuing always beneath the extremity of the horizontal radius of the axle, will oppose the same resistance, as though it acted upon the invariable arm of a lever, in the manner of a bucket of water, which is drawn up out of a well by a rope, winding on a roller, and the power required to raise the weight will be always the same.

If the radius of the wheel, of which these hollow canals serve as bent spokes, be equal to the height through which the water is to be raised, and consequently equal to the circumference of the axle, or shaft, the power will be to the load of water reciprocally as the radius of a circle to its circumference, or directly as 1 to $6\frac{1}{2}$ nearly. M. de la Faye recommended the machine to be composed of four of these canals, but it has often been constructed with eight. The wheel is turned by the impulsion of the stream upon float-boards fixed on the circumference of the wheel, and the orifices of the curvilinear canals dip one after another into the water which runs into them; and as the wheel revolves, the fluid rises in the canals, until it is as high as the centre: it then runs out in a stream from the holes in the axis, and is received into the trough fixed beneath the axis; and thence it may be conveyed by pipes or troughs to the required situation.

By this construction, the weight to be raised offers always the same resistance, and that is the least possible, while the power is applied in the most advantageous manner which the circumstances will admit of. These conditions being both fulfilled at the same time, furnish the most desirable perfection in a machine. This machine raises the water by the shortest way, namely, the perpendicular or vertical line, and in this respect is preferable to Archimedes's screw, where the water is carried up a crooked and inclined path; and besides this each curved channel in this wheel empties all the water it receives in every revolution, while the screw of Archimedes delivers only a small portion of the fluid with which it is charged, being often loaded with twenty times as much water as is discharged at one rotation, and thus requiring an increase of labour when a large quantity is intended to be raised by it. The horn-wheel would be one of the most perfect machines for raising water, were not its powers confined to such altitudes as the semi-diameter of the wheel.

The *flash*, or *fen-wheel*, comes next to be described.—This is a vertical wheel, made exactly like those water-wheels for turning mills which are called breast-wheels, and in the same manner the wheel is surrounded at the lower quadrant by a curved sweep of masonry or breast, to which the floats of the wheel are fitted with the greatest accuracy, but do not absolutely touch. This wheel, being turned round in a direction contrary to that in which a water-wheel turns, will carry water before its floats, and raise it up against the breast until it runs over the same. The operation is just the reverse of the water-wheel; and the only difference in the construction of the two machines is, that the flash-wheel requires no shuttle to be placed at the top of the breast, because the water must be allowed to run freely away from the top of the breast; but the water-wheel requires a shuttle or sluice to regulate the quantity of water which shall flow to the wheel.

It is by this kind of machine that the extensive fens of Holland are drained; and in Lincoln and Cambridgeshire they are also used very extensively. They are, in general,

worked by the power of the wind, and are on a very large scale.

Mr. Smeaton made a horse-machine on this plan, which raised thirty-three hogheads *per* minute, to the height of four feet and a half, when it was worked by four horses; but a sluice was placed in the channel which admitted the water to the wheel, so as to supply the water in a greater or lesser quantity; and by this means, the same machine could be adapted to the power of three or two horses. The crown or top of the breast, over which the water was delivered, was not elevated to the full height to which the water was to be raised, but it was laid twelve inches beneath the surface, and the body of water which the wheel raised up was sufficient to drive this depth of water before it; but to prevent the return of the water when the mill ceased working, two pointed doors were placed in the channel leading from the wheel, like the gates of a canal-lock: these doors opened freely, to let the water pass, but would shut and stop the water from returning. The proportions of this machine were as follows:

Diameter of the track in which the	}	26 feet 8 inches.
horses walked - - -		
Great cog-wheel fixed on the per-	}	72 teeth 9 feet dia-
pendicular axis - - -		
Trundle worked by the wheel -	-	35 teeth $4\frac{1}{2}$ feet diam.
Diameter of the water-wheel on the	}	14 feet.
same axis as the trundle - - -		
Breadth of the wheel - - -	-	2 feet 2 inches.
Number of its floats - - -	-	42

The floats did not point to the centre of the wheel, but formed tangents to a radius, equal to about half the radius of the wheel. The floats of the wheel were very exactly fitted to the channel or pit in which it worked, so as not to touch.

The *bucket-wheel* is a very ancient method of raising water; but it cannot lift water to a greater height than its own diameter. The last machine was the reverse of the breast water-wheel, and the present is the reverse of the over-shot water-wheel, for the circumference of the wheel is surrounded by buckets, which dip in the water beneath the wheel, and take up water, which they discharge at the top of the wheel into an elevated trough or reservoir. The wheel is mounted upon an horizontal axis, and turns upon pivots; it is put in motion by the force of a current of water striking the float-boards fixed on the circumference of the wheel; or if there is no current in the water, it may be moved by making the wheel hollow within for a man to walk in it, as is common in some kinds of cranes, or the wheel may be turned by horses. The rim, or circumference of the wheel, is made hollow, and is divided into several compartments, to form a number of boxes or buckets; each bucket has an opening into it at that end which will be the most advanced when the wheel turns; and from this opening, a spout or trough projects in a direction parallel to the axis of the wheel. When the wheel revolves, the buckets dip into the stream, and become filled with water; but as the mouths or spouts are at the upper end when the buckets rise out of the water, they cannot escape, and each bucket carries up its charge of water to the top of the wheel; but the buckets will have then become inverted, and the spouts or openings being at the lowest part, that they discharge the water sideways through the spouts into a trough properly placed to receive it, and then the buckets descend empty till they dip into the stream and are refilled. The objection to this machine is, that the buckets begin to pour out the water
some

some time before they arrive at the greatest height of the wheel; and, therefore, the trough is of necessity placed lower than the diameter of the wheel, or a considerable portion of the water would be lost, and in any case part of the water is raised above the level of the trough.

Spanish Bucket-Wheel.—Mr. Townsend, in his Travels through Spain, describes a simple machine which is used at Narbonne for watering of gardens. The water is raised by a vertical wheel, which is twenty feet in diameter, on the circumference of which is fixed a number of little boxes or square buckets, for the purpose of raising water out of the cistern communicating with the canal below, and to empty it in a reservoir above, placed by the side of the wheel. The buckets have a lateral orifice to receive and to discharge the water. The axis of this wheel is embraced by four small beams, crossing each other at right angles, and tapering at the extremities so as to form eight little arms. This wheel is near the centre of the path in which the mule walks, and contiguous to the vertical axis, into the top of which the horse-beam is fixed; but near the bottom of this axis it is embraced by four little beams, forming eight arms, similar to those above described, on the axis of the water-wheel. As the mule which they use goes round, these horizontal arms, supplying the place of cogs, take hold each in succession of those arms which are fixed on the axis of the water-wheel, and keep it in rotation. This machine may be made very cheap, and will throw up a great quantity of water, yet undoubtedly it has two defects; the first is, that part of the water runs out of the buckets, and falls back into the well after it has been raised nearly to the level of the reservoir; and the second is, that a considerable proportion of the water to be discharged is raised higher than the reservoir, and falls into it only at the moment when the bucket is at the highest point of the circle, and ready to descend.

The *Persian wheel with swinging buckets* is free from some of the defects of the last machine. The buckets are loose, and each hangs from the circumference of the wheel by a pin, on which it swings or turns freely; and as the bucket is suspended by its upper part, it will hang perpendicular, with the mouth upwards, in all positions of the wheel. From the time it dips in the water and is filled, until the bucket arrives at the upper part of the wheel, it is carried by the motion of the wheel against the edge of the trough, and inclined so far as to discharge its contents into the trough. (See *Persian Wheel*.) The pins are fixed into the circumference of the wheel, and project sideways therefrom a sufficient distance to support the buckets, and carry them over the elevated trough. Sometimes the wheel is made with two rims, and each bucket is suspended upon an axis between them: the end of each axis passes through the rim of the wheel, and is bent to form a short lever, which is carried by the motion of the wheel against a fixed rail, and thus inclines the bucket to discharge the contents into a trough which is fixed to the rims of the wheel immediately beneath the bucket, and has a spout projecting at the side of the wheel, to carry the water sideways and deliver it into the trough, which is fixed at the side of the wheel for its reception.

As the Persian wheel is a very effective machine in situations where the elevation is required to be but small, the following directions, given by M. Belidor for its construction, are worthy of attention: first fix the diameter of the wheel something greater than the altitude to which the water is to be raised; fix also upon an even number of buckets, to be hung at equal distances round the periphery of the wheel; and mark the position of their centres of motion in such a

manner, that they will stand in corresponding positions in every quarter of the circle. Suppose vertical lines drawn through the centre of motion of each bucket in the rising part of the wheel, and they will intersect the horizontal diameter of the wheel in points, at which, if the buckets were hung, they would make the same resistance to the moving force, as they do when hanging at their respective places on the rim of the wheel. Thus, supposing there are eighteen equidistant buckets, then while eight hung on each side of a vertical diameter of the wheel, there would be eight on the other side, and two would coincide with that diameter: in this case, the resistance arising from all the full buckets would be the same as if one bucket hung on the prolongation of the horizontal diameter, at the distance of twice the sine of 20° + twice the sine of 40° + twice the sine of 60° + twice the sine of 80° , these being the sines to the common radius of the wheel.

To know the quantity of water that each one should contain, take four-ninths of the absolute force of the stream, that is, four-ninths of the weight of a prism of water whose base is the surface of one of the float-boards, and whose height is equal to that through which the water must fall in order to acquire the velocity with which the stream moves. This is the power which should be in equilibrio with the weight of water contained in the buckets of the rising semicircle. Then say, as the sum of the sines mentioned above is to the radius of the wheel to the centre of the float-board, so is the power just found to a fourth term, one-half of which will be the weight of water that ought to be contained in each bucket. Lastly, the velocity of the float-board of the wheel will be to that of the stream nearly as one to two and two-fifths, and from this the number of revolutions it will make in any determinate times may be known, and of consequence the quantity of water the wheel will raise in the same time, since we know the capacity of each bucket, and the number of them which will be discharged in every revolution of the wheel. See *Persian Wheel*.

The Chinese Bucket-Wheel.—Sir George Staunton, in his account of the Embassy to China, gives the following description of a bucket-wheel, which is different from any we have met with in the hydraulic collections, and constructed with that simplicity which distinguishes the Chinese inventions. Two hard-wood posts or uprights are firmly fixed in the bed of the river, in a line perpendicular to its banks. These posts support the pivots of an axis of about ten feet in length: this is the axis of a large wheel consisting of two unequal rims, the diameter of the rim which is nearest to the bank being about fifteen inches less than that of the outer rim; but both rims dip into the stream, while the opposite points or top of the wheel rise above the elevated bank over which the water is to be raised. This double wheel is framed upon the axis, and is supported by sixteen or eighteen spokes, inserted obliquely into the axis near each extremity, and crossing each other at about two-thirds of their length. They are there strengthened by a concentric circle, and are fastened afterwards to the two rims. The spokes inserted in the interior extremity of the axis reach to the outer rim, and those proceeding from the exterior extremity of the axis reach to the inner and smaller rim. Between the rims and the crossings of the spokes is a triangular space, which is woven with a kind of close basket-work, to serve as ladle-boards, or floats. These successively receiving the current of the stream, obey its impulse, and turn round the wheel.

The buckets which take up the water are small tubes or spouts

WATER.

spouts of wood attached to the two rims of the wheel, and having an inclination of about twenty-five degrees to the horizon, or to the axis of the wheel. The tubes are closed at their outer extremities, which are fixed to the larger rim, and open at the opposite end. By this position the tubes, which in the motion of the wheel dip into the stream, have their mouths or open ends uppermost, and fill with water. As that segment of the wheel rises upwards, the mouths of the tubes attached to it will alter their relative inclination, but not so much as to let their contents flow out until such segment of the wheel arrives at the top. The mouths of these tubes are then relatively depressed, and they pour the water into a wide trough placed on pivots, from whence it is conveyed, as may be wanted, among the plantations of canes.

The only materials employed in the construction of this water-wheel, except the nave or axis, and the posts on which it rests, are afforded by the bamboo. The rims, the spokes, the ladle-boards or floats, and the tubes or spouts, or even the cords, are made of entire lengths, or single joints, or large pieces, or thin slices, of the bamboo. Neither nails, nor pins, nor screws, nor any kind of metal, enter into its construction: the parts are bound together firmly by cordage of slit bamboo. Thus, at a very trifling expence, is constructed a machine, which, without labour or attendance, will furnish, from a considerable depth, a reservoir with a constant supply of water, adequate to every agricultural purpose.

These wheels are from twenty to forty feet in diameter, according to the height of the bank, and consequent elevation to which the water is to be raised. A wheel of thirty feet is capable of sustaining with ease twenty tubes or spouts, of the length of four feet, and diameter of two inches in the clear. The contents of such a tube would be equal to six-tenths of a gallon, and the twenty tubes would hold twelve gallons. A stream of a moderate velocity would be sufficient to turn the wheel at the rate of four revolutions in one minute, by which would be lifted forty-eight gallons of water in that short period; or in one hour, two thousand eight hundred and eighty gallons; and sixty-nine thousand one hundred and twenty gallons, or upwards of three hundred tons in a day. This wheel is thought by Sir George to exceed, in most respects, any machine yet in use for similar purposes. The Persian wheel, with loose buckets suspended to the edge of the rim or fellics of the wheel, so common in the south of France, and in the Tyrol, approaches nearest to the Chinese wheel, but is vastly more expensive, and less simple in its construction, as well as less ingenious in the contrivance. In the Tyrol there are also bucket-wheels for lifting water in a circumference of wood, hollowed into scoops; but they are much inferior either to the Persian or Chinese wheel.

Chain of Buckets.—This machine consists of a number of buckets attached to a chain or rope, the ends of which are united together. The chain is conducted over a wheel, which is turned by some animal or mechanical power; and the chain hangs down from this wheel into the well from which the water is to be drawn. The buckets at the lower part of the chain become filled, and, by the motion of the chain, the buckets attached to one part of the chain will ascend full of water, whilst those on the opposite side are descending empty, with their mouths downwards. When the full buckets of water turn over the upper wheel, they discharge their contents into a trough fixed near the wheel. The most convenient way of discharging the water is to make the upper wheel hollow, with divisions in it like the tympanum; and the buckets, when they turn over, will

pour their contents into the hollow segments of the wheel, and it will run off through a hollow in the axis made for that purpose. The advantage of the chain of buckets over the wheel is, that the chain can be made to descend in a well, or small space, where the wheel could not; also, that the chain may be used for greater depths than would be practicable for a wheel.

The *Spanish noira* is a chain of buckets or earthen jars.

Mr. Townsend informs us, in his journey through Spain, that the noira consists of an endless band or girdle, passing over a sprocket-wheel: the band is long enough to reach eighteen inches or two feet below the surface of water in a well. All round this band, at the distance of about fifteen inches, are fixed jars of earthen-ware, which, as the band turns, take up water from the well, and pour it into a cistern fitted to receive it. A little ass, going round in a circular walk with ease, turns a trundle, which gives motion to a cog-wheel, fixed on the same axis with the sprocket-wheel, on which the band is hung, and with which it turns. This machine produces a constant and considerable supply of water, at a small expence, and with very little friction. As the air would obstruct the entrance of water into these earthen jars or bottles, each jar has a little orifice in its bottom, through which the air escapes; but then water runs out also, and a certain quantity falls back into the well.

It is true, as the jars rise in one straight line, the water which runs out of the superior jar is caught by that which is immediately below it, yet still there is a loss; and, besides this inconvenience, the whole quantity is raised higher than the upper reservoir, at least by the diameter of the sprocket-wheel, because it is only in their descent that the jars are emptied.

The *screw of Archimedes* is a machine on a principle very closely allied to the horn-wheel; but the curved channels are wrapped spiralwise round an axis, which is placed on an inclined position, with the lower end immersed in the water which is to be raised, and the upper end placed over the edge of the reservoir into which the water is to be delivered. When this cylinder is turned round, it will take water up in its spiral channel, and raise it gradually to the elevated end, and discharge it into the reservoir. (See SCREW.) Although this machine is simple in its general manner of operation, its theory is attended with some difficulties.

If we conceive that a flexible tube is rolled regularly about a cylinder, from one end to another, this tube or canal will form a screw or spiral, of which we suppose the intervals of the spires or threads to be equal to one another. Suppose this cylinder placed with its axis in a vertical position, if we put in at the upper end of the spiral tube a small ball of heavy matter, which may move freely, it is certain that it will follow all the turnings of the screw from the top to the bottom of the cylinder, descending always as it would have done, had it fallen in a right line along the axis of the cylinder; only it will occupy more time in running through the spiral.

If we suppose the cylinder placed with its axis horizontally, and we again put the ball into one opening of the canal, it will descend, following the direction of the first demi-spire, until it arrives at the lowest point in this portion of the tube, and then it will stop: for the weight of the ball has no other tendency than to make it descend in the demi-spire. The oblique position of the tube, with respect to the horizon, causes the ball, in descending, to advance from that extremity of the cylinder whence it commenced its motion to the other extremity. When the ball is arrived at the bottom of the first demi-spire, if we cause the cylinder to turn on its axis, without changing the position

of that axis, and in such manner that the lowest point of the demi-spire on which the ball presses becomes elevated, then the ball falls necessarily from this point upon that which succeeds, and becomes lowest; and as this second point is more advanced towards the second extremity of the cylinder than the former one, the ball will be advanced towards that extremity by this new descent, and so on, that it will at length arrive at the second extremity. Moreover, the ball, by constantly following its tendency to descend, has advanced through a right line, parallel and equal to the axis of the cylinder; and this distance is horizontal, because the sides of the cylinder were placed horizontally.

But suppose the cylinder had been placed oblique to the horizon, and turned on its axis continually in the same direction, it is easy to see that the ball will move from the lower end of the spiral tube towards the upper end, although it is actuated solely by gravity, for this causes it to occupy the lowest point of the first demi-spire; and when it is abandoned by this point, as it is elevated by the rotation, and will roll by its weight upon that point which has taken its place, this succeeding point is further advanced towards the elevated extremity of the cylinder than that which the ball occupied just before; consequently the ball, while following its tendency to descend, will be always more and more elevated, by virtue of the rotation of the cylinder. Thus it will, after a certain number of turns, be advanced from the lower extremity to the upper, or through the whole length of the spiral; but it will only be raised through the vertical height, determined by the obliquity of the position of the cylinder.

Instead of the ball, let us now consider water as entering by the lower extremity of the spiral canal, when immersed in a reservoir. This water descends at first in the canal solely by its gravity; but the cylinder being turned, the water moves on in the canal to occupy the lowest place, and thus, by the continual rotation, is made to advance further and further in the spiral, till at length it is raised to the upper extremity of the spiral, where it is expelled. There is, however, an essential difference between the water and the ball; for the water, by reason of its fluidity, will adapt itself to the form of the spiral, and, after having descended by its heaviness to the lowest point of the demi-spire, will rise up on the contrary side to the original level; on which account, more than half one of the spires may be filled with the fluid.

The most simple method of tracing a screw or a helix upon a cylinder is well known to be this:—Take the height or length of a cylinder for the perpendicular leg of a right-angled triangle, and make the base or horizontal leg equal to as many times the circumference of the cylinder as the screw is to make convolutions about the cylinder itself; then draw the hypotenuse to complete the triangle. Suppose this triangle to be enveloped about the surface of the solid cylinder, the perpendicular leg being made to lie parallel to the axis of the cylinder, and the horizontal leg or base to fold upon the circumference of the cylinder, even with its base; then the hypotenuse or sloping side of the triangle will form the contour of the screw. If a tube be formed according to the direction of this spiral, and a small ball put into it when the cylinder is placed upright, the ball would roll to the bottom with the same velocity, and the same force, as it would have descended upon a plane surface, inclined in the same degree as the hypotenuse of the triangle which we have supposed, when the base thereof is horizontal. But suppose the cylinder be inclined in such degree, that the hypotenuse of the said triangle would be horizontal instead of the base, as the angle which the

threads of the screw make constantly with the base of the cylinder is just equal to that inclination, the threads at their point of smallest inclination will be parallel to the horizon; so that there being nothing to occasion the ball to roll towards either end, it will remain immovable, supporting the cylinder to be at rest; but if the cylinder be turned on its axis in one direction, the ball (abstracting from friction) will move the contrary way, in conformity with the first law of motion. The inclination which we have just assigned is the least we can give, so that the ball shall not descend of itself; but if we augment this inclination, then, by turning the cylinder, the ball will always have a descent on one side, and will in consequence roll towards the elevated end of the same, and will mount by descending. The reason is very simple: the plane which carries it makes it rise more, in consequence of the rotatory motion, than it descends by virtue of the force of gravity. It is obvious, from what has been remarked, that this screw can never raise water, when the angle which the central line of the spiral makes with the base of the cylinder is larger than the angle which the base of the cylinder makes with the horizon.

The ratio of the weight of the ball to the force which is necessary to make it rise by turning the screw, is as the vertical space through which the weight is raised to the space passed through by the power in moving it. Suppose the moving force acts at the circumference of the cylinder, the space passed over by that force will be equal to as many times the circumference of the cylinder as the number of convolutions of the helix. Let the diameter of the cylinder be 14 inches, the vertical altitude of the upper end of the cylinder above the lower end 12 feet, or 144 inches, and 12 convolutions of the spiral: let the cylinder be so placed, that the inclination of the axis is greater than the inclination of the spiral to the axis, and let the weight to be raised be a 48 lb. ball. The circumference of the cylinder will be nearly 44 inches, and the 12 turns equal to $12 \times 44 = 528$ inches, for the space the power must move through. Hence we have 528 inches : 144 inches :: 48 lbs. : $13\frac{2}{3}$ lbs.; the measure of the requisite force to be applied at the surface of the cylinder. If the moving force describes a circle whose diameter is three times that of the cylinder, or acts at a winch whose distance from the axis of motion is 21 inches, that force will then be reduced to $\frac{1}{3}$ of $13\frac{2}{3}$ or $4\frac{2}{3}$ lbs. which is less than one-tenth of the weight of the ball. In this investigation, no notice is taken of the friction upon the pivots, or of the effects of the air included in the spiral: yet if the spiral had been folded upon a cone instead of a cylinder, or if it had been formed of a flexible tube of varying diameter, these effects would have been important: some of them are considered in our account of the spiral pump.

The Archimedes' screw is a machine so frequently employed in hydraulic architecture, as to deserve particular directions for constructing it. The simple pipe wrapped round a cylinder will not afford any considerable supply of water, and therefore a hollow barrel must be made with one or two spiral partitions running in it, like the spiral stair cases used in church steeples.

Vitruvius has given minute directions for the construction of the water-screw, and Mr. Smeaton's directions, which are very similar, are as follow:—For a screw of 18 inches diameter, use a solid cylinder of six inches diameter as an axis, upon the surface of which cut a double helix, forming two separate grooves round the axis of about three-quarters of an inch wide and deep, so that the grooves in going once round will advance about sixteen inches, and in consequence

consequence the two grooves will be eight inches apart from middle to middle, measuring parallel to the length of the cylinder. Into these grooves drive and fasten pieces of board, so as to form radii or sectors of a circle of eighteen inches and a half diameter, and so moulded as to be a little upon the twist, to answer the different inclinations of the helix, at the different distances from the centre. These pieces being jointed together, and to the axis, so as to fill the whole groove from one end of the axis to the other, form a double screw; then apply narrow boards longitudinally, reaching from one end of the screw to the other. The boards should be about four inches broad, and formed concave within, answerable to a circle of eighteen inches diameter. These boards are marked one by one at the places where they touch the spiral boards, and are then grooved about a quarter of an inch, to admit the ends of the radius pieces which form the screw. When all the boards are put together they form a cylinder of eighteen inches diameter, which is hooped on the outside, in the manner of a tub or cask; and in order that the hoops may properly drive on the outside, at the same time that the inside forms a complete cylinder, the longitudinal pieces are made rather thicker in the middle than at the ends.

Archimedes' screw may be used for other purposes than raising of water. It might be adapted with advantage in raising cannon-balls from a ship to a wharf, and with the addition of a bevel-wheel or two and their pinions, might be worked either by men or horses. Sometimes Archimedes' screw instead of being worked by men at a winch, is turned by means of float-boards fixed on the circumference of a wheel placed at its lower end, upon which a stream of water acts. If the water has a moderate fall, it will have sufficient efficacy to turn two screws, one above another. The top of the lower screw and the bottom of the upper screw may act one upon the other, by means of a wheel upon each, with an equal number of teeth taking into each other. In this case the upper screw will turn in a contrary direction from the lower, and consequently the spiral tube must be wound about the cylinder in an opposite direction. A solid wheel, or a light wheel with a heavy rim, turning upon the middle of the screw as an axis, will operate like a fly, and in some cases be very useful.

Mr. Smeaton made a machine to raise water by an Archimedes' screw for the royal gardens at Kew, which was on a large scale. The screw was twenty-four feet long, two feet six inches in diameter, and raised the water perpendicularly fourteen feet nine inches. The central cylinder, or shaft of the screw, was ten inches diameter; the distance between the threads, including the thickness of the helix, was twelve inches and a half; and as there were two spiral passages, each spiral advanced twenty-five inches along the cylinder at every turn; each spiral contained twenty-seven quarts at every turn, the screw therefore gave out fifty-four quarts at every turn which it made.

This screw was turned by means of a trundle or pinion from a horse-wheel, with the intervention of two moveable joints, to change the direction of the axis from the horizontal to the direction of the axis of the screw, which was inclined at an angle of about thirty-eight degrees to the horizon. The diameter of the horse-track was twenty-five feet, half of which was the length of the effective lever upon which the horses acted. The great cog-wheel on the axis of the levers was fourteen feet diameter, with 144 cogs, and the trundle which it turned twenty-three cogs, so that the screw made about six turns for one of the horse-wheel.

This machine was worked by two light horses, with very

great ease, and they made three turns *per* minute; but if at all urged, could make the screw turn twenty turns *per* minute, and at that rate of working raised 300 hogheads *per* hour.

The *Water-screw*, described in our article SCREW, does not differ from the screw of Archimedes in its principle, but as the screw turns round within a fixed barrel, the water is liable to leak back in part.

Drawing Water by Buckets.—The methods which we have hitherto described are only adapted to raise water to small elevations; but by means of buckets, water may be drawn from very great depths. The most simple case is that of a man with a bucket or other vessel in his hand, stooping down to lower the empty bucket into a pond, as low as he can reach, and drawing it up full of water.

The first improvement which would occur would be to suspend the bucket by a rope, and draw it up by means of a long lever, or otherwise, if the depth was greater, by continuing the rope over a pulley, so that the man could easily draw the end of it; and this would be farther improved when two buckets were suspended at the opposite ends of the rope or chain, so that one being drawn up full of water, an empty one would be let down at the same time. This method is applicable to the deepest well, and is very effective. The addition of a windlass and crank would be a successive improvement, and could be made to act either singly, to draw up one bucket, or double, to let down an empty bucket at the same time it drew up another loaded with water.

The drawing up of a bucket by a rope and pulley is so simple and obvious as to need no explanation. The bucket should be of such a size that it will not weigh above twenty-six pounds, and will therefore contain nearly half a cubic foot of water. For although a man could with ease raise a much greater weight, yet he would be unable to draw it up so quickly, or to work at it throughout the day; and what he would gain by the increased quantity of water, he would lose in the time which it would require to draw up the bucket, and in the time he would require to rest himself from his fatigue. If the rope is conducted horizontally, and the man takes it over his shoulder and walks along the ground, his force will be applied in a much more effective manner than by simply hauling the rope over a pulley; and a horse may be applied in the same manner with a larger bucket, and there is perhaps no better mode of applying the force of a horse for a deep well. The bucket should not in this case weigh above a hundred and twenty pounds, or it must not contain above two cubic feet to enable the horse to draw it with that velocity which is most natural to him.

When a windlass is employed to wind up the rope, the winch or crank, which is applied to the axis of it, can be made much larger than the radius of the windlass, and in consequence the power may be increased so much that a larger bucket may be drawn, which is some advantage, because less time will be lost in stopping to fill and empty the bucket, otherwise nothing is gained in drawing up a large bucket, because it must move slower in proportion to its increased weight; but in all cases the length of the handle should be about fourteen or sixteen inches, to enable a man to turn it with ease, and the weight of the bucket must be so adapted to the size of the windlass, that the power required at the handle will not be above thirty pounds or even twenty-five pounds, if a man is to work continually for six or eight hours in a day. For example, suppose the bucket is about forty-six pounds weight, and the handle sixteen inches long, then as 46 is to 25, so is 16 to $8\frac{3}{4}$ nearly; from

which deduct half the thickness of the rope, and it leaves the proper radius for the roller or windlafs. A rope of the proper size for this purpose will be about two inches and a half in circumference, or rather more than three-quarters of an inch in diameter; hence the diameter of the barrel will be $16\frac{3}{4}$. If a fly-wheel is applied to the axis, it will be an advantage to equalize the force which the man applies, because some positions of a crank or handle are less favourable than others for the exertion of a man's strength. It is most advantageous to employ two buckets, and as the rope for one unwinds whilst the other winds up, the weight of the two buckets balance each other, and the man has only the weight of the water to draw up.

Bucket-Machines for deep Wells.—When a machine to draw water by buckets is made on a larger scale, the windlafs is placed perpendicularly, and levers applied to it at the lower end, which may be actuated either by men, or by horses walking round in a circle on the ground, and drawing or pushing the end of the lever; in this way a powerful machine may be made, and if the depth is very considerable, it is a very good method. Many methods have been proposed to make the buckets fill themselves when at the bottom of the well, and empty when at the top: the best is to suspend the bucket in an iron loop or bow, like the handle of a pail, but this should be made so long, that the pins on which the cask or bucket hangs, shall be but little above the centre of gravity of the bucket when loaded with water; in consequence, when the bucket is drawn up to the top, one edge of it is caught by a hook fixed on the edge of the cistern into which the water is to be delivered, and the bucket still continuing to be drawn up whilst the hook detains one edge, the bucket is thereby overturned, and its contents discharged into the reservoir. It is requisite for this plan, that the bucket be made, by some contrivance, to prevent itself always in the same direction to the hook, so that it will be seized and overturned thereby: one method is to fix upright pieces of wood or iron in the well on each side of the bucket, and the pivots on which the bucket is poised project on each side beyond the iron loop on which the bucket hangs, and enter into grooves formed in these pieces, so as to be guided in the ascent and descent of the bucket. Another method is to make the rope of the bucket double for some feet immediately above the bucket, that is, the rope divides into two ends, each of which is made fast to the opposite side of the iron loop in which the bucket is suspended: the rope is made to pass through a narrow opening in a piece of plank, which will admit the double rope to pass freely, provided the bucket comes up in the required position; but if it does not, then the forked rope will be acted upon by the sides of this narrow opening in such manner, as to turn the bucket round to the required position.

To make the bucket fill readily at the bottom of the well, a simple valve is made in the bottom, which opens upwards and admits the water, but shuts when the bucket is drawn up out of the water. In the Transactions of the Society of Arts, vol. xii. is a description of a machine by Mr. Ruffel, in which the bucket, when it is drawn up to the top of the well, acts upon a lever, and causes a moveable trough to run across the well beneath the bucket; and then as the bucket rises higher, a trigger, which belongs to the valve in the bottom of the bucket, is intercepted by a fixed piece of wood, so as to open the valve, and the water runs out of the bucket into the moveable trough which conveys it into the reservoir: when the bucket begins to descend, it allows the levers to return, and the moveable trough retreats from beneath the bucket, and allows it to descend again into the well to bring up a fresh charge. The moveable trough is made

to run backwards or forwards over the mouth of the well, by means of wheels or rollers, on which it is supported, and these wheels run upon pieces of wood laid across the well.

Indian Method of drawing Water by a leathern Bucket.—Dr. Roxburgh of Calcutta has given us a description of a method of raising a large quantity of water from a deep well by means of one or two buffaloes or bullocks, which is in common use in many parts of Hindoostan, where the wells are too deep for the lever. A pulley is erected over the well to receive a rope, which the animals draw by walking along an horizontal path in order to elevate a large bucket, and they return towards the well to lower it down: the bucket is made of leather, like a long funnel, extended at the top or mouth by a square frame of wood, or by a hoop, and the lower end terminates in a small open tube, which is flexible, and can be turned up; in which case, if the orifice of the tube is kept as high or higher than the mouth of the bucket, no water can escape through the tube, it is in this condition that the bucket is drawn up full of water: the end of the tube has a cord fastened to it, which is conducted over a roller fixed on the edge of the trough into which it is desired to deliver the water, and which trough must be at least the length of the bucket beneath the great pulley that is fixed over the well. The opposite end of the cord is tied to the great rope near the point where the buffaloes draw, and the cord is of such length as to hold the orifice of the tube rather above the mouth of the bucket, until the tube is drawn up to the roller. When the cord draws the tube over the roller, and leads its end into the trough as the bucket continues to be drawn up, it is raised above the level of the trough, by which means the whole of the water will make its escape through the orifice of the tube into the trough: when the bucket is let down again, the flexible tube returns over the roller, and the cord holds up its orifice above the top of the bucket.

Defaguliers, in the second volume of Experimental Philosophy, describes a very simple contrivance to raise water by a bucket; which is this, to one end of a rope is fixed a large bucket, having a valve in its bottom opening upwards; to the other end of the same rope is fastened a square board, something like the scale-board of a balance, but large enough for a man to stand upright in it; the cord is made to pass over two pulleys, each of about fifteen inches diameter, and fixed in such manner, that as the bucket descends, the scale ascends with equal velocity, and *vice versa*. The scale is made to run freely between four vertical guide rods, passing through holes at its four corners, and when the bucket is lowered down into the lower water-cistern in order to fill with water, the scale stands nearly level with the horizontal plane of the upper reservoir to which the water is to be raised. When the bucket is full, a man steps into the scale, and his weight, together with that of the frame, exceeding the weight of the vessel and its contained water, will give an ascending motion to the bucket, and causes the valve in its bottom to close. When the bucket is raised to the proper height, a hook which is fixed at the edge of the upper reservoir catches into a halsp at the side of the bucket, and turns it over, to cause it to empty its water into the upper cistern, or into a trough, which conveys it where it is required: at this time the man and the scale have arrived at a platform, which prevents their further descent, and the man must remain in the scale till he finds the bucket above is empty, when he steps from the scale, and runs up a flight of stairs to the place from which he descended: the bucket in the mean while, being somewhat heavier than the scale, descends again to the water, and raises the frame to its original position; thus the work is

is continued, the man being at rest during its descent, and labouring in the ascent.

Defaguliers employed in this kind of work a tavern-drawer, who had been used to run up and down stairs; he weighed 160 pounds, and was desired to go up and down 39 steps of $6\frac{1}{2}$ inches each (in all about 21 feet) at the same rate he would go up and down all day. He went up and down twice in a minute, so that allowing the bucket, with a quarter of a hoghead of water in it, to weigh 140 pounds, he is able to raise it up through 21 feet twice in a minute, which is equivalent to the whole hoghead raised $10\frac{1}{2}$ feet in a minute, and rather exceeds what Defaguliers assigned as a maximum of human exertion; from experiments made with a mercurial pump. He recommends that the man in the scale should weigh one-fifth or one-sixth more than the weight of the water in the bucket, in order to give him a preponderance to bring up the bucket with a proper velocity.

Balance Buckets.—This is an ingenious contrivance for raising water by the power of a small fall of water: suppose a wooden lever twenty feet long, poised upon a centre at five feet from one end, one arm will then be five feet long, and the other fifteen, or three times. At the extremity of the long arm a small bucket is fixed, and at the extremity of the short arm another bucket, which is rather more than three times as great in capacity: the lever is so poised, that it will place itself in an horizontal position when both the buckets are empty; but suppose that in this situation a small spout of water runs into each bucket, when they become both filled, the larger bucket at the end of the short arm will overweigh the smaller one, because it holds more than three times as much water; in consequence, the larger bucket will descend and move the lever into a perpendicular situation, by which means the small bucket is raised fifteen feet above the level of the spout at which it received the water, whilst the great bucket has descended five feet beneath its source of supply. Both the buckets are suspended to the ends of the lever on pivots, so that they can readily be turned over to discharge their contents; this takes place when the lever arrives near its vertical position: the small bucket is caught by a hook, and overturned into the elevated trough which is to receive the water, and immediately the lower bucket is emptied by similar means. The long end of the lever is now the heaviest, and in consequence the lever returns to its horizontal position, in which it remains until the buckets are both full, and then it makes another stroke. A simple contrivance is applied to stop the running of the spout of water during the time that the lever is in motion, to prevent waste of the water.

The *losing and gaining Buckets* is a similar machine to the preceding, but admits of raising the water to a greater height, because chains and wheel-work are employed instead of a lever. This machine will raise water sufficient to serve a gentleman's seat, with an overplus for fountains, fish-ponds, &c. A machine of this kind can be erected wherever there is a spring affording a small supply of water, and having even so small a fall as ten feet. It is possible, by this invention, with the loss of part of the water, to raise the rest, to supply a house, or any place where it is required; but, of course, it must be in a less quantity than the fall of water which is to actuate the machine, nearly in the same proportion as the place to which the water is to be raised is higher than the fall of the spring. For example, the fall of one hoghead through ten feet will raise about one-sixth of a hoghead to the height of forty feet. This machine had been conceived by Schottus a great many years ago, and he gave a draught of it. It is described in Leopold's *Theatrum Machinarum Hydraulicarum*, 1720; but it was never

put in execution to any good purpose in England, till Mr. George Greaves, a carpenter, erected an engine upon this principle, about 1730, for Sir John Chester, baronet, at his seat at Chickley, in Buckinghamshire; a sketch of which is given at *fig. 13, Plate Water-Works*. A small spring of water, supplying four gallons *per* minute, is conveyed seventy-two yards, by a gutter, into a cistern N, containing about twelve gallons. This water has a descent to the other cistern at R, ten feet below X; from the latter, the waste is conveyed off along H, by a drain or sewer. The descent of part of the water through this ten feet is the motive force to work the machine. A, B, are two copper pans, or buckets, of unequal weights and sizes, suspended by chains, which alternately wind off, and on the two multiplying-wheels Y and Z, whereof the wheel Y is smaller in diameter, and Z larger, in proportion to the different lifts each bucket is designed to perform. A house is built over the well or cistern, with three floors, for the conveniency of fixing the parts of the engine. On the uppermost floor is fixed a frame of timber 2 2, in which the moving parts are supported, as is shewn, (part being broken off in the figure, to explain the work): across this frame lies an horizontal axis G, three feet and a half long, moving on two gudgeons in brasses. Upon this axis are framed three wheels; first, the small wheel Y, which is two feet diameter, and shrouded, or made with a raised rim at each side: the edge of the wheel is five inches broad, and shod with iron. Upon the wheel Y is fixed a chain, made very flat and flexible, which, after it has wrapped once round the wheel, is then made double, that it may lie on each side of the edge part, the double parts having a sufficient opening between them to admit the single part, and this prevents fretting or galling, and keeps the chain exactly perpendicular: from the extremity of the double part is hung a long rod of iron, at the bottom of which the great bucket A is fixed. The largest wheel Z on the axis is six feet diameter, and one inch and a half broad on the face, which is also shrouded: this wheel is not circular, but spiraled two inches, both in the sole and in the shrouds; so that its radius at the least part is two inches less than three feet. Upon the large wheel Z is fixed a smaller chain, to suspend the bucket B: it is made like the former, and so arranged, that when the wheel Z has made one revolution from left to right, the spiral sole will take up a certain length of the chain. After this length, the lower or remaining part of the chain has cross-bars fixed to it, at equal distances, which fall upon the edges of the shrouds into notches plated with iron: by this means, and by the help of the spiral, this part of the chain is not only prevented from riding upon the other, but helps to equiponderate the increase of weight of the other chain of the bucket A. A third wheel *r*, three feet ten inches diameter, is fixed on the axis G, between the other two wheels: it is shrouded like the others, and is spiraled three-fourths of an inch; it receives a rope, the lower end of which goes about a wheel *d*, of two feet diameter, to which that end is fixed, and on the axis, *d*, of this wheel is another, *t*, one foot diameter, and to this is fastened a rope, which goes down upon the quadrant *ab*, which carries a sliding weight in a box at the extremity of the arm Q; the quadrant *a* moves on the axis *b*, and the rope descending from the wheel *t*, is guided between iron plates, upon the circumference of the quadrant. The box, at the end of the arm Q, contains a sliding lead weight, to counter-balance the weight of the chains, by keeping an exact equilibrium in every position of the machine. Besides the action of the quadrant, the motion is regulated by wheel-work, like that of a jack; thus, upon

one end of the axis *G*, is a strong iron wheel *M*, giving motion to a pinion *m*, and by means of a wheel and worm *n* and *o*, to a fly *P*, which regulates the motion of the engine, and prevents any improper acceleration from the unwinding of the chains. The small bucket *B* is made of copper, about five gallons in capacity; it has a valve in the bottom, by which the bucket will be filled when it descends into the water of the cistern *N*. The bucket is suspended in an iron link, or handle, upon two pivots, so that it can be very easily turned over upon them. This happens when it is drawn up to *F*, the edge of the bucket catching a hook which overturns it, and discharges the contents into the trough *W*, at an elevation of thirty feet above *X*, and whence it is conveyed by pipes wherever it is wanted. The great bucket *A* is likewise made of copper, and contains about fifteen gallons when drawn up to the position *A*: it is filled with water from a valve, or sluice, in the side of the cistern *N*, which is then opened by a bent lever, whereof the end projects, so that the bucket will lift it up. In the bottom of the bucket is a spindle-valve, which is opened when the bucket has descended to *R*, by the end of its spindle resting on the bottom of the well. Iron rods are fixed vertically to guide both the buckets, which have ears with brass rollers in them, and inclose three sides of each, which is square, and they are thus caused to ascend and descend in a perpendicular line, and no other.

The operation of the machine is as follows:—When the buckets are empty, they are stopped, as shewn in the figure on a level with the spring at *X*, whence they are both filled with water at the same time, in the manner just described.

The greater of the two *A*, being the heavier, when full preponderates, and descends ten feet from *C* and *D*, and the lesser *B*, depending from the same axis, is at the same time weighed up or raised from *B* to *F* thirty feet.

Here, by catching the hook *F*, the small bucket discharges its water into the trough *W*, and thus suddenly losing weight, it lets the great bucket down an inch lower, and the valve in the bottom is opened, so as to let out its water, which runs waste by the drain below at *H*. The bucket *B* being then empty, is so adjusted as to overweigh, and descending steadily as it rose, betwixt the guiding-rods, it brings or weighs up *A* to its former level at *X*, where both being again replenished from the spring, they thence proceed as before. And thus will they continue constantly moving, (merely by the circumstantial difference of water and weight, and without any other assistance than that of sometimes giving the iron-work a little oil,) so long as the materials shall last, or the spring supply water.

The steadiness of the motion is, in part, regulated by the fly *P*, which not only keeps the engine to an equal velocity, but by its running forwards, after the buckets are quite up or down, holds them steady till they are completely filled or emptied, and prevents them recoiling back too soon. In order to counterbalance the weight of the chains in every position, the wheels *r*, *d*, and *t*, are so calculated, that during the whole performance up and down, they let the quadrant *a* move no more than one-fourth of a circle; by which contrivance, as more or less of the chains which suspend the buckets come to be wound off their respective wheels *Y* and *Z*, this weight gradually increases its action as a counterbalance, and so continues the motion equable and easy in all its parts. The spiraling of the wheels *Y* and *Z* help, in some measure, to regulate the weight of the chains in every position, as they act in winding on and off the wheels; but the quadrant *ab*, and lever with the weight *Q*, complete the equilibrium, by acting with the greatest force, because the lever is in the horizontal position

when the chain of the great bucket *A* is all down, and weighing upon the wheel, the weight *Q* then acts with its whole weight upon the wheel *t*, as that chain is drawn up, its acting weight is thereby diminished, and the lever of the weight *Q* is moving down towards its perpendicular, whereby the weight *Q* diminishes equally in its influence on the motion of the wheel *r*, until it hangs perpendicular, and its weight ceases to act; but the sliding-weight then runs down in its box, to keep the rope tight, the sliding-weight being attached to the end of the rope, and not to the lever. At the first return, or re-ascent of the great bucket, the weight *Q* is drawn up to a shoulder, before any motion is given to the lever of the quadrant; but whilst the long chain of the small bucket evolves from its wheel *Z*, the acting-weight of the quadrant is continually increasing, and at the same time the other chain of the great bucket wrapping itself upon the wheel *Y*, its acting weight is decreasing. The lever of the quadrant rising higher, brings the line of direction of the weight *Q* farther from the centre of the quadrant, and so lays a greater force or obstruction to retard the wheel *r*, and continually keeps a counterbalance.

This engine, at a slow motion, carries up one bucket full in five minutes; but if the spring ran double the quantity, it would go up twice in the same time, and an engine of this kind may be made to raise one hoghead *per* minute, or more, if required, the consumption of water is less than what is spent by a water-wheel to raise an equal quantity of water to the same height.

The Endless Rope to raise Water.—This is a most simple contrivance, and will raise up a small quantity of water from a very considerable depth. A soft hemp or hair-rope, with the ends spliced together, is suspended over a large wheel, which is turned by a handle; the rope must hang down into the well, and reach some depth into the water, and a similar wheel may be placed beneath the surface of the water for the rope to pass under; but this is not necessary when the length of the rope is such, that its own weight will make it apply close to the upper wheel. The upper part of the rope must descend through a tube, which is fixed in the bottom of the cistern, or reservoir, to prevent the water running down with the rope; the tube is of such size as to fit the rope very nearly, but not to cause any considerable friction. The rope is put in motion by turning the handle of the wheel, and the motion must be in such a direction, that the rope where it passes through the tube in the cistern shall descend.

The consequence is, that the water in the well adheres to the rope, and surrounds it like a film, or covering of water; but when the rope passes over the wheel, some of the water is thrown off by the centrifugal force, and falls into the reservoir, and that part of the water which escapes the action of the wheel is separated from the rope by the tube through which the rope passes; for it is to be observed, that the film of water which surrounds the rope is put in motion, whilst it is in the well, by the lateral adherence of the water to the rope, which motion being continually kept up, is sufficient to overcome the gravity of the water; but if any body is presented to the rope, so as to resist the motion of the water, without obstructing the motion of the rope, the water will fly off, and, losing its motion, will obey the action of gravity, and fall down.

The velocity with which the rope requires to be moved, will depend upon the depth from which the water is to be raised. The length of that part of the rope which is immersed in the water is also of some consequence, for it must be such, that the rope will act upon the still water which

which immediately furrounds it, until it has put that water in motion with nearly the same rapidity as the rope, and then such portion of water will accompany the rope; but this cannot take place without communicating a slower motion to a much larger quantity of water, which will also accompany the rope with a slower motion; but being too far removed from the rope to have its motion accelerated, or even maintained, its velocity will continually decrease, until it ceases to ascend, and then it will begin to run back. But this is to be understood only of that part of the water which is too far distant from the rope to have its motion fully maintained by the lateral action of that water which is nearer to the rope, and which moves with nearly the same velocity as the rope. If the rope is examined at the point where it rises above the surface of the water, it will be found to be surrounded by a column of water which is of a considerable size at the base, but diminishes as it rises upwards, somewhat in the form of a trumpet, so that at a few feet in height it is but little larger than the rope. This column of water is composed of several laminæ, each moving with a different velocity: for instance, the interior part moves nearly as quick as the rope, the water which is more distant from the rope moves slower, until there must be a part in which the water remains immovable, and all the water which is beyond this, and on the outside of the column, runs downwards, and falls back into the well. On this account, the machine loses a considerable part of the power which is applied to it without producing an adequate effect.

This machine was invented by the *Seur Vera*, in France. A machine was made by him with a wheel three feet diameter, and a hair-rope of half an inch diameter, the well was ninety-five feet deep. A man could turn the wheel sixty times *per minute*, which gives a velocity of five hundred and fifty-five feet *per minute* for the rope. It brought up six gallons *per minute*, but was severe labour for one man. When the wheel made fifty turns, and the rope moved four hundred and seventy-one feet *per minute*, the machine still raised a considerable quantity of water; but if the motion was reduced to thirty turns, or two hundred and eighty-two feet *per minute*, it brought up scarcely any water. A rope of hair is preferable to hemp, because it is less subject to decay; and when a hemp-rope begins to rot, it communicates a taint to the water.

The *Sucking-Pump* has a valve at the bottom of the barrel, and also another valve in the piston, which is called a bucket, because it brings up the water before it. This pump does not raise water when the bucket is let down, but only when it is drawn up, which is in some cases an inconvenience; and another objection is, that it cannot raise water to a greater height than the place where the power is applied, because there must be an opening for the pump-rod to come out at, and the water would flow out at the same opening, if it was raised as high. This inconvenience is remedied by

The *Lift-Pump*, which has a valve in the bucket, the same as the sucking-pump, but it differs from it in the manner of communicating the force to the piston or bucket: one way of effecting this is to make the barrel open at the lower end, and the rod from the bucket, instead of being fixed to the upper side of the bucket, is fixed to the lower side, and comes out beneath the surface of the water in which the barrel is immersed. Rods are jointed to this, and rise up parallel to the barrel, in order to be attached to the lever by which the pump is to be worked: the fixed valve is placed at the top of the barrel above the bucket: this is the old-fashioned lift-pump.

The *Lift-Pump with a Stuffing-box*, called sometimes a jack-head pump, is exactly the same as the sucking-pump, except that the top of the barrel is covered by a lid, which has a hole in the centre for the rod to pass through: the rod is made very smooth and true, and the hole is so formed as to contain collars of leather, which fit close round the rod, and prevent the escape of any water by the side of the rod. The water mounts up a pipe which communicates sideways with the upper part of the barrel.

Another form of lift-pump has been recently introduced, in which the piston is solid, having no valve in it, and the rod passes through a stuffing-box or collar of leather in the top of the barrel, the bottom of the barrel being open. Two pipes are made to communicate sideways with the barrel at the upper part, one of which brings water from the well into the pump when the piston descends, and has a valve in it to prevent the return of the water; the other pipe conveys the water away from the barrel when the piston is drawn upwards, and this is likewise furnished with a valve to prevent the return of the water.

One advantage of this kind of pump is, that both valves are situated in boxes near the top of the barrel, and can be examined and repaired at any time by taking off the doors or covers of the boxes; but in pumps where there is a valve at the bottom of the barrel, it sometimes happens that the valve fails, and requires to be repaired, when the water in the well stands higher than the cover or door of entry to the valve: in this case, some other means must be used to reduce the water in the well, or else the pump must be drawn up out of its place, which, in large works, is very difficult. Another advantage is, that the apertures of the valves may be made of any required dimensions to let the water pass freely through them; but when the water must come up through a valve in the bucket or piston, the passage through the valve must necessarily be much smaller than the barrel, to allow a proper lodgment all round for the valve and also for the leathers.

The *Force-Pump*.—This is made with a solid piston, like the last, but the barrel is open at the top, where the piston-rod comes out. There is a valve at the bottom of the barrel to admit the water into it, and a pipe, which turns sideways out of the barrel at bottom, and has a valve to prevent the water returning into the barrel, to convey the water to whatever place it is to be forced to. The force-pump raises water only when the piston is pressed down, whereas the lift-pumps and sucking-pumps raise the water when the buckets are drawn up.

The *Lift and Force-Pump of M. De la Hire*.—This is the union of the two last pumps in one, for both these pumps work with a solid piston, and the barrel of the force-pump is open at top, and the barrel of the lift-pump is open at bottom; hence the same barrel and piston may be made to serve for both. This pump throws up water equally when the piston-rod is drawn up or when it is forced down, and is most proper for the double-acting steam-engine. It has the advantage of raising twice the quantity of water that any of the other pumps will raise, and with the friction of only one piston; also the valves admit of being made of sufficient size to allow the passage of the water without any unnecessary resistance.

Force-Pump with a solid Plunger.—This was invented by *Mr Samuel Morland*, and does not differ from the force-pump last described, except in the manner of fitting the piston to the barrel. Instead of the barrel being bored truly cylindrical within, and the piston fitted into it so as to slide up and down, and provided with leathers to make a close fitting, the piston is made of a cylindrical form, and very nearly

as large as the hollow barrel into which it descends, but it does not touch the inside of the barrel. To make the close fitting, the outside surface of the cylindrical piston, or plunger, as it is called, is made very true and smooth; and it is surrounded by a collar of leathers fixed at the top of the barrel, so that no water can leak out of the barrel between the plunger and the leather collars; at the same time that the plunger can freely move up and down through the collars, and will thereby increase or diminish the capacity of the barrel, to produce the same effect as if the piston fitted close into the barrel.

The principal circumstance to be attended to in this pump is the construction of the collar of leathers. To retain these leathers in their places, the top of the barrel must be made with a flaunch, and pierced with holes to receive screw-bolts. Upon this flaunch two rings of metal are applied one over the other, with similar holes: the internal opening in the lowest ring is exactly the size of the plunger, and that of the upper one a little larger. Two rings of soft leather are cut out to correspond with the metal rings, except that the central holes are rather smaller than the plunger: to prepare the leather, it is soaked in a mixture of oil and tallow for some hours. One of these leather rings is laid on the pump-flaunch, and one of the metal rings placed above it; the plunger is then thrust down through the leather, which turns the inner edge of the leather ring downwards; the other leather ring is then slipped on at the top of the plunger, and the second metal ring is put over it, and then the whole are slid down to the metal ring; by this the inner edge of the last leather ring is turned upwards.

The metal rings and leathers are now fixed on the flaunch by the screw-bolts; and thus the leathern rings are strongly compressed between them, and make a close joint with the top of the barrel; and as the holes through the leathers are smaller than the plunger, they grasp the plunger so closely that no pressure can force the water through between them. The lower metal ring just allows the plunger to pass through it, but without any play, so that the turned-down edges of the lower leathern ring cannot come up between the plunger and the lower metal ring, but are lodged in a conical enlargement, which is made round the inner edge of the upper part of the barrel; and in like manner the turned-up edges of the upper leather are received in the hole of the upper metal ring, which hole is made larger than the plunger, to leave a space all round for these edges: it is on these trifling circumstances that the great tightness of the collar depends. To prevent the leathers from shrinking by drought, there is usually a little cistern formed round the head of the pump, and kept full of water.

This kind of pump is preferable to any other, where the pressure to be overcome is very considerable. The hydrostatic presses are constructed on this principle. See PRESS.

Pistons or Buckets for Pumps.—A good piston should be as tight as possible, and should have as little friction as is consistent with this indispensable quality. The bucket of the common sucking-pump, when carefully executed, possesses these properties in a high degree, and is the model for other kinds of pump-buckets, or pistons, in which leather can be employed. This bucket is in the form of a truncated cone, with a hollow through the centre of it, which is half as large as the outside, at the largest part; it is generally made of wood not liable to split, such as elm or beech, but in the best kind of pumps is made of metal. The small or upper end of it is cut away at the sides, so as to open into the hole through the centre of it, and form an arch, by which it is fastened to the iron rod or spear of the pump, and within the arch the valve or clack is situated. The lower end of

the conical part may be covered with a hoop of brass, which fits the barrel of the pump very exactly; the bucket is also surrounded with a ring or band of strong leather, fastened to the wood with nails, and firmly retained by the brass hoop which is driven down on the bucket from the upper or the smaller end of the cone, and binds the leather fast on the wood; but the leather being wider than the brass, the edge of the leather rises upwards and surrounds the wood: this part of the leather is made to turn outwards, like a cup or hollow cone, which, at the upper end, is rather larger than the barrel, so as to spring against the inside of the barrel when the bucket is put into it. The leather must be of uniform thickness all round, so as to suffer equal compression between the wood of the bucket and the working barrel, but this compression is very slight, because it is the upper edge of the cup which applies most closely to the barrel. The seam or joint of the two ends of the band of leather must be tapered, and made to overlap and lie very close, without increasing the thickness, but not sewed or stitched together, as that would occasion bumps or inequalities, which would spoil its tightness; and no harm can result from the want of sewing, because the two edges will be squeezed close together by the compression in the barrel; nor is it by any means necessary that this compression be great, for it occasions friction, and causes the leather to wear through very soon at the edge of the bucket, and it also wears the inside of the working barrel, which soon becomes enlarged in that part which is continually passed over by the piston, while the mouth remains of its original diameter, and then it is impossible to thrust in a piston which shall completely fill the worn part. A very moderate pressure is sufficient for rendering the pump perfectly tight, because the pressure of the water makes the leather cup apply itself close to the barrel all round, and even adjust itself to all its inequalities. Suppose it to touch the barrel in a ring of an inch broad all round, this is a trifle, and the friction occasioned by it not worth regarding; yet this small surface is sufficient to make the passage perfectly impervious, even by the pressure of a very high column of incumbent water: for let this pressure be ever so great, the pressure by which the leather is forced against the inside of the barrel will always exceed it, because, in addition to the pressure of the water, the leather will always press against the barrel by its own elasticity, the top of the cup of leather being made rather larger than the interior of the barrel.

This method of applying leather pistons is found to be preferable to any other, because if the leather is pressed against the barrel by any other means than the force of the column of water, the pressure will always be too great or too little.

Pumps which are to raise hot water cannot be leathered, because the leather would shrivel up; in this case, strong canvas cloth is sometimes used instead of leather; but as this will not hold water perfectly, such pumps are generally packed with hemp, in the same manner as the piston of steam-engines.

Pump without Friction.—When the height to which the water is to be raised is small, a pump may be constructed in which the piston does not require to be fitted closely into the barrel, nor are any leathers required. The barrel of this pump must be as long as the whole height to which the water is to be raised, and as much more as the length of the stroke of the piston. The piston is a solid piece of wood, fitted to the barrel as closely as it can be without actually touching the inside, and may be either square or round, but a square trunk and a square beam of wood are best, if the pump is made of wood. The piston must be as long as the barrel,

barrel, so that when it is let down it will occupy the whole interior space of the barrel, except that small space which is left between the inside of the barrel and the piston, to avoid actual contact. The bottom of the barrel has a valve in it which opens upwards, and a pipe proceeds from the lower part to convey away the water to the reservoir into which it is to be raised by the pump. This pipe is provided with a valve, to prevent the return of any water which has passed through it, but the greatest elevation of the water in the reservoir must not be quite so great as the top of the barrel. When this pump is fixed for work, the lower end of the barrel must be immersed in the water of the well at least as much as the whole length of the stroke, so that the lower end of the piston will never rise above the surface of the water in the well, and upon this circumstance the action of the pump depends; for when the piston is drawn up, the water flows through the valve in the bottom by its gravity, and fills the space which is left by the drawing up of the piston; when the piston descends, it displaces from the barrel all this water, and forces it up the side-pipe into the reservoir. It is true that a small portion of water rises in the space between the barrel and the piston, but this small quantity cannot escape, because the top of the barrel rises higher than the surface of the water in the reservoir.

Dr. Robinson, who we believe first described this pump, observes that it is free from all the difficulties which are experienced in common pumps, from want of being airtight. Another is, that the quantity of water raised is very nearly equal to the power expended; for if there is any want of accuracy in the work, which occasions a diminution of the quantity of water discharged, it also makes an equal diminution in the force which is necessary for pushing down the plunger. The doctor mentions a machine, consisting of two such pumps, the pistons of which were suspended from the arms of a long beam or lever, the upper side of which was formed into a walk, with a rail on each side. A man stood on one side of the centre of the lever, until the piston of the pump at that end sunk to the bottom of its barrel, and of course the piston of the pump on the opposite side of the centre was drawn up; he then walked slowly up to the other end of the walk upon the beam or lever, the inclination being about twenty-five degrees at first, but gradually diminished as he went along, and passed on the opposite side of the centre of motion, so as to change the load of the beam. By this means he made the piston at the other end go to the bottom of its barrel, and so on alternately, with the easiest of all exertions, and what a man is most fitted for by his structure. With this machine a feeble old man, weighing 110 pounds, raised 7 cubic feet of water $11\frac{1}{2}$ feet high every minute, and continued working eight or ten hours every day. A stout young man, weighing nearly 135 pounds, raised $8\frac{1}{3}$ cubic feet to the same height; and when he carried 30 pounds conveniently slung about him, he raised $9\frac{1}{4}$ feet to this height, working ten hours a day, without greatly fatiguing himself. This exceeds Desaguliers' maximum of a hoghead of water ten feet high in a minute, in the proportion of 9 to 7 nearly. This pump is limited to very moderate heights, and in such situations it is very effectual.

The *mercurial pump* is a species of lift-pump, in which mercury is employed to make a close fitting between the piston and the barrel, and thus avoid the friction of leathers, and prevent loss of water.

This pump was originally invented by Mr. Joshua Haskins, and was improved by Desaguliers, who described it in

the Philosophical Transactions for 1722, N^o 370. p. 5; and he has also given every detail of the construction in his Experimental Philosophy, vol. ii. p. 491.

In this pump the barrel is inverted, that is, it is open at the bottom, like the first lift-pump which we have mentioned; and it has also two pipes communicating with the upper end of the barrel, one to bring up the water from the well, and the other to carry it up to the reservoir: each pipe is provided with its valve, to prevent the return of the water. The barrel must be made of iron, and as thin as is consistent with the strength of the metal. The piston is a cylindrical plug of wood, fitted to the barrel so as to fill it, but not to touch the sides. This piston is fixed perpendicularly in the centre of a hollow cylinder of iron, which is rather larger within than the outside of the pump-barrel, so that an annular space is left all round between the solid piston or plug and the inside of the cylinder, into which space the pump-barrel can enter, and will fill it very nearly. The annular space is then filled with mercury. This compound piece, consisting of the hollow cylinder, with the smaller solid cylinder within it, forms the piston; and to this the power which is to work the pump is applied by means of chains, which suspend it from the short arms, so that if the lever is moved, the piston will rise up and down. When the piston is applied in its place, and the inverted pump-barrel is received into the annular space between the solid and hollow cylinders, the mercury therein will make a close fitting between the solid piston and the inside of the barrel, so as to prevent any water passing between them; and the ascent and descent of the piston will produce an alternate contraction and dilatation of the internal capacity of the working barrel, in the same manner as a solid piston would do, if it was closely fitted to the inside of the barrel with leather all round.

As the water exerts a pressure on the mercury, to force it out of the annular space in which it is lodged, the depth of the annular space and length of the barrel which descends into it must be adapted to the height to which the water is intended to be elevated; so that the column of mercury which it will contain, without raising the mercury so high as to run over the edge of the external cylinder, shall always exceed one-thirteenth part of the height to which the water is to be elevated; the weight of mercury being more than thirteen times the weight of an equal quantity of water.

That there may be less mercury used, the pump-barrel should be made of plate-iron, turned on the outside, and bored within; the outer cylinder of the piston should be bored, and the inner one turned; and if the work be well performed, eight or ten pounds of mercury will be sufficient, though the bore of the barrel, or diameter of the column of water which is raised, is six inches. Less than six pounds of mercury would suffice, if there were two barrels, in order to keep a constant stream. This will very much lessen the expence of mercury, which would otherwise be an objection against this pump; and by making the inner and outer cylinder of hard wood, as box, or *lignum vite*, the expence may still be reduced. But if the engine be very large, cast-iron bored will be proper for the outer cylinder, and cast-iron turned on the outside for the inner cylinder or plug, and hammered iron bored and turned for the middle cylinder.

There is an objection, which seems at first to take off the intended advantage of this engine, *viz.* that instead of the friction of the leather of a piston, when we lift up the piston to make a stroke, the resistance necessary to make the mercury to rise on the outside of the barrel in the outer cylinder

of the piston is at least as great as the friction we avoid. Defaguliers says, that resistance is never greater than the weight of a concave cylinder of mercury, whose height is the greatest to which the mercury rises in the said outer cylinder, and the base is the area of the barrel itself. This weight in a pump of 6 inches bore is equal to $57\frac{1}{2}$ pounds, and, therefore, it would appear to be greater than the resistance arising from the friction of a piston. But if it be considered, that in the descent of the piston for sucking, the mercury shifts immediately into the inside of the barrel, rising to the same height therein, and still keeping the same base, the weight of $57\frac{1}{2}$ pounds helps to press down the piston, and facilitates the overcoming of the force of the atmosphere, or suction of the pump; consequently, the weight of the mercury being balanced is no hindrance, whether the pump works with a double or with a single barrel.

There remains only then the hindrance by loss of time, whilst the mercury changes from the outside to the inside of the barrel, at the beginning of any stroke. Defaguliers states this to be one-fifty-second part of the stroke, and that he found the best pumps then in use generally lost near one-fifth of the water that they ought to have given, according to their number of strokes.

Notwithstanding the high terms in which this author and others have spoken of the mercurial pump, it can only be considered as an ingenious suggestion, for the expence of mercury would be too great for the actual application of any such machine in practice; and in respect to friction, it would have a considerable share of resistance in plunging the piston into the mercury, although there would be no actual rubbing of hard substances together. This resistance would arise in the rapid running of the mercury from the inside of the barrel to the outside, and back again, at the beginning of each stroke.

The machine is exceedingly ingenious and refined, and there is no doubt but that its performance will exceed that of any other pump which raises the water to the same height, because there can be no want of tightness in the piston, and friction is in a great measure avoided. But these advantages are but trifling. The expence would be enormous; for with whatever care the cylinders are made, the interval between the inner and outer cylinders must contain a very great quantity of mercury. The middle cylinder must be made of iron-plate, and without any seam, for mercury dissolves every kind of solder. For such reasons, it has never come into use. But although we have professed to describe only the machines in actual use, it would have been unpardonable to have omitted the description of an invention, which is so original and ingenious; and there are some occasions where it may be of use, such as nice experiments for illustrating the theory of hydraulics: it would be the best piston for measuring the pressures of water in pipes, being in fact the same principle as the barometer.

Sector pumps are those in which the piston is made to move upon a centre, like a door upon its hinges. The piston is inclosed within a vessel shaped like the sector of a circle, which forms the body of the pump, and which is divided by the piston into two compartments. The piston is fitted, so that it can move backwards and forwards on its centre of motion, without suffering any water to pass by it; and by this motion it will alternately enlarge or contract the capacities of the two compartments, so as to draw in water through pipes and valves properly situated, and force it out again at other pipes. These kinds of pumps are difficult to

construct, and have no advantages over the pumps with straight barrels, except for the engines for extinguishing fire. See that article for a description and figure of Mr. Rowntree's, which is one of the best of this kind.

Rotative Pumps.—As most of the first movers for hydraulic machinery act with a rotative motion, it would be very desirable to have a pump which would at once employ the rotative force to the purpose of raising water. Many schemes have been proposed, and much ingenuity displayed in these inventions; but hitherto no one has been brought to such perfection as to be equal to the pumps with straight barrels. In Ramelli's work, published in 1588, several rotative pumps are described; and Leopold has made a collection of them in his "Theatrum Machinarum Hydraulicarum," vol. i. They are all upon one common principle, viz. a hollow cylinder or drum closed on all sides; within this another smaller cylinder is inclosed, and the interior cylinder is placed out of the centre of the hollow cylinder, so that the interior cylinder touches the hollow one at one point of the circumference; but at all other points there is a considerable space between the two. The interior cylinder is provided with four or six valves or leaves, which are united to it by hinges, and, when folded close up to the cylinder, will form a smooth and circular circumference; but if the leaves are opened out, they will reach to the interior surface of the hollow cylinder. When the interior cylinder is turned round by a handle applied to the axis, the valves sweep round within the hollow cylinder, and in this motion perform the office of pistons, because they close up to the internal cylinder, in proportion as they approach towards the point where the internal cylinder touches the hollow cylinder; and the same vanes open out again, after they have passed that point. In this way the spaces between the valves form a number of cavities, which alternately expand and contract in their capacity, and in consequence they will draw up water through a pipe which is inserted into the hollow cylinder, and force it out at another pipe, so as to raise up a continual stream.

The machine is sometimes varied, by making the hollow cylinder of an elliptical form: in other cases, the valves, instead of moving upon hinges, are made to slide in straight lines from the centre of the revolving cylinder; but in either case, the action is the same. The common defect of all these rotatory pumps is, that it is very difficult to pack them so as to be tight, and they have more friction than any other kind of pump.

The *centrifugal pump*, invented by Mr. Erskine, may be called a rotative pump, but it is on a different principle from all other pumps. A perpendicular pipe has another joined to it, in form of the letter T: the lower end of this pipe being immersed in water, and the whole filled with water, it is turned round on the perpendicular stem as an axis; the water contained in the horizontal arms will, by its centrifugal force, fly out, and draw a constant stream of water up through the perpendicular pipe. See *Centrifugal Pump*.

Spiral pump, or *Zurich machine*, is a hollow drum or cylinder turning on a horizontal axis, and partly plunged in a cistern of water, like a very large grind-stone. The interior space of this cylinder or drum is formed into a spiral canal, by a plate coiled up within it, like the main-spring of a watch in its box, only that the spirals are situated at a given distance from each other, so as to form a spiral passage of uniform width. (See fig. 11. *Plate Water-Works*.) This spiral partition is well joined to the two circular ends of the cylinder, and no water can escape between them. The inner

inner end or central part of the spiral passage communicates with the axis, which is hollow at one end, and communicates with the vertical pipe which is to convey the water to the elevated reservoir. The outermost turn of the spiral passage begins to widen at about three-fourths of a circumference from the open end, and this gradual enlargement continues for nearly a semicircle; this part being called the horn. The passage then widens suddenly in form of a scoop or shovel. The cylinder is so supported, that this scoop may, in the course of a rotation, dip several inches into the water, and take up a certain quantity of water before it emerges again. This quantity is sufficient to fill the enlarged part called the horn, and is also nearly equal in capacity to one turn of the outermost uniform spiral. The vertical pipe is connected with the axis by a turning joint, so as to admit of the rotation of the axis, at the same time that it will not allow of the escape of any water.

When this cylinder is turned round by a handle applied to the extremity of the axis, a portion of water which the scoop takes up at every turn, will continually advance in the spiral, until it arrives at the centre; it will then pass through the hollow in the end of the axle, and will rise upwards in the vertical pipe; and in the intervals between the periods when the scoop dips into the water, the horn will become filled with air, and the succeeding portion of water which is taken in will carry the air before it, so that the water rises in the vertical pipe mixed with air. See SCREW.

Dr. Robinson, in his account of this machine, recommends the rising pipe to be of small bore; for if the pipe is so large as to allow the air to escape freely upwards through the water, the machine will raise the water to a certain height, proportioned to the number of turns of the spiral, and to their diameter; but if the pipe be narrow, so that the air cannot rise freely, it will rise in the pipe almost as slowly as the water. By this circumstance, the water mixed with the air becomes of a less specific gravity, as it were, and can be raised to a much greater height than it could be raised by the mere pressure of the columns of water and air in the different turns of the spiral. This is effected with hardly any augmentation of the power, but if the air, after being compressed, is suffered to escape, all the force exerted to compress it will be lost. The entrance into the rising pipe should be no wider than the last part of the spiral; and it would be advisable to divide it into four channels by a thin partition, and then to make the rising pipe very wide, and to put into it a number of slender rods, which would divide it into several slender channels, that would serve completely to entangle the air among the water. This procedure will greatly increase the height to which the heterogeneous column may be carried.

Another Form of the Spiral Pump.—When the main pipe is very high, the former construction will require either an enormous diameter of the drum, or many spiral turns of a very narrow pipe. In such cases, it will be much better to make the spiral in the form of a cork-screw, than of a flat form like a watch-spring; or, the pipe which forms the spiral may be wrapped round the frustum of a cone.

We regret that we have had no opportunity of making experiments upon a machine of this kind, as its principles of action, though treated of by many authors, are not described in a satisfactory manner in any works which we have read.

The *chain pump* is an effective means of raising water, and with the advantage of a continuous motion. It is generally made with a square or round barrel, placed in a perpendicular position. The chain is furnished with several pistons of the same figure as the barrel, which are fixed at small distances asunder upon the links of the chain. The ends of

the chain are united together, and it is extended between two wheels, one fixed at the upper end of the barrel, and the other at the lower end; but sometimes only the wheel at the top is used. These wheels have forks fixed on the circumference, which are so contrived as to receive one half of each of the flat pistons in the intervals between the forks, whilst the forks take hold of the links of the chain, and draw them up, when the wheel is turned round by means of a handle applied to the axis. The pistons on the chain are made accurately to fill the section of the barrel, at the lower part near the water, and also for a few feet upwards; but above this, the barrel is made larger, so that the pistons rise up free: indeed, the upper part of the barrel is only to contain the water which is brought up by the pistons, and may, therefore, be square, or of any other figure. The lower end of the barrel is immersed in water, and the chain being caused to circulate by turning the wheel, each piston, as it enters into the lower or bored part of the barrel, will bring up water before it in the barrel; which water will rise in the upper part of the barrel, till it runs over the top; and as the pistons succeed each other in a regular succession, they produce a constant stream. Chain pumps are chiefly used in ships, where they are worked by the force of men turning winches. (See PUMP.) In other situations they are moved by horses, and sometimes by the impulse of a stream of water. They are so contrived, that by the continual folding in of the pistons, when they enter into the bottom of the barrel, stones, dirt, or whatever comes in the way, may be cleared off. On this account they are often used to drain ponds and sewers, or to remove foul water, when no other pump could be employed.

The greatest disadvantage in the chain pump is the friction of the chain, and of the pistons, which is greater than in other pumps; because several pistons are moving in the barrel at the same time, and also because the pistons do not admit of the application of the cup-leathers, which we have described. The edges of the cups would fold up when they enter into the barrel, and get between the edge of the piston and the barrel. The pistons are, therefore, made with a thick piece of leather, which is placed between two round plates, which form the piston or faucer, as it is called; the leather is cut round to the size of the barrel, so that the edge of the leather may be applied to the inside of the barrel. In this way, its tightness must depend wholly upon the force with which the leather is squeezed into the barrel, and it occasions great friction to make the pistons sufficiently tight.

Another variety of the chain pump is an endless rope, with stuffed cushions fastened upon it at regular intervals. By means of two wheels or drums, the rope is made to circulate, and the cushions are drawn up in succession through the barrel, and each one carries some water before it.

The chain pump is found to raise a greater quantity of water to the same height, when the barrel is placed in an inclined position, than when vertical. M. Belidor recommends the barrel to be placed at an angle of 24 degrees with the horizon, and the distance between the pistons to be equal to their diameter. The reason of this advantage is, that an inclined pump acts with less friction, because the pistons need not be so exactly fitted, but they will, by their weight alone, apply closely to the bottom or lowest side of the inclined barrel; whereas the pistons of the vertical pump must exactly fill the barrel, or the water will leak down from one to the next in a constant stream.

Bellows-Pump.—A pair of leathern bellows may be employed as a pump, if a suction-pipe is applied to the lower valve, and another pipe to the nozzle, with a valve to

prevent the water returning into the bellows after it has been driven out by closing the bellows. This kind of pump has been frequently proposed, and the advantages of dispensing with barrels and pistons loudly insisted upon; but the resistance of the leather in folding, and the loss of water by leakage; and above all the want of durability, will always prevent the adoption of such pumps.

The Pump with a Diaphragm of Leather, which does not slide in the Barrel.—This is very nearly allied to the bellows-pump. The best form for constructing it is fully described in our article *SHIP'S Pump*, where the invention is attributed to Benjamin Martin; but we find the same thing was long before applied by Messrs. Goffet and De la Deuille, in France. (See Belidor's *Arch. Hydraulique*, vol. ii. p. 120.) This is a good pump, but is not durable, because the constant strain on the leather will cause it to crack.

Sucking-Pump, which gives out a continual Stream.—Mr. Smeaton applied the following simple and effectual expedient to make a single sucking-pump deliver the water equally in the descent of the bucket as in its ascent. The pump-rod was enlarged, by surrounding it with a cylinder of wood at the part where it rose above the surface of the water contained in the cistern at the top of the pump. This cylinder of wood was of such diameter, that its section was equal to half the area of the pump-barrel at the place where the bucket worked. When the bucket was drawn up, and raised water into the cistern at top of the pump, the wood cylinder, which was attached to the pump-rod, rose up out of the water in the cistern, and thereby made place in the cistern for one-half of the water which was brought up by the bucket, and in consequence only one-half of the water ran out at the spout of the cistern; but when the bucket moved downwards, in order to fetch another stroke, this cylinder of wood displaced from the cistern half as much water as the pump brought up in the former instance, and consequently an equal quantity of water was given out at the spout in either case.

If the pump is worked by the force of a man working a simple lever, then he will make the down-stroke of the bucket in less time than the up-stroke, and in this case the area of the cylinder should be made less than half the area of the barrel of the pump. It must be observed, that this contrivance is only a remedy for the unequal efflux of water from the sucking-pump, and that the power required to work the pump is still left unequal in the up-stroke and down-stroke, because it is only in raising up the bucket that the water is drawn from the well below; and that water which runs out at the spout when the bucket descends, is drawn from the cistern at the top of the pump, and not from the well. When the pump is worked by a man with a lever, this inequality of the resistance is advantageous, because a man can exert his force most conveniently when he depresses the end of the lever to draw up the bucket; also, in a single-acting steam-engine, the principal power is exerted to draw up the bucket.

In machines worked by wind, water, or horses, the moving force is uniform, and the resistance must, by some means, be made uniform also, or the machine will move by sudden starts. A sufficient weight may be applied to the opposite end of the lever to counterbalance one-half of the force necessary to draw up the bucket; this weight will tend to diminish the force of drawing up the bucket, and when the bucket descends, and the machine would otherwise have nothing to do, it will have to raise up the weight ready to aid it in the succeeding stroke. Or a fly-wheel may be applied: but a still better method is to employ two pumps to act alternately, by which means the resistance is continual, and the efflux of

water also. When two sucking-pumps are employed, they may be combined together, by making them both draw from a common suction-pipe, and both may be made to lift the water into the same cistern. Or two or three force-pumps may be combined together, as is described in the article *PUMP*, in order to produce a continuous stream.

Air-Vessel for equalizing the Discharge of Water from Pumps.—This is the most perfect contrivance for effecting that purpose. It is a close vessel of any figure, which will contain air, and is made to communicate with the pipe which conveys the water away from the pump. This communication must be made at the lower part of the air-vessel, so that the water will have free ingress and egress from it. The air in this vessel will be compressed into a smaller space, in proportion to the column of water which the pump has to raise; and by its elasticity endeavouring continually to regain its former space, it will act as a spring to equalize all sudden motions of the water through the pipe; for in any pump which acts by a barrel and piston, the water will be propelled by starts; and even if two or three barrels are combined together so as to produce a continual efflux of water, such efflux will not be perfectly equal during all the periods of the motion.

The evil of this may appear trifling and so it would be merely with respect to the discharge of the water; but it must be considered that the mass of water contained in a long pipe is very great, and that it requires a very considerable force to put this mass in motion with that velocity with which it must flow through the pipe. Now if the operation of a pump is by starts, the mass of water in the main-pipe will remain at rest, pressing on the valve during the time that the piston is withdrawn from the bottom of the working barrel. In this case, the force necessary to put the water in motion must be expended at every stroke, because if the column comes to rest only for an instant, it must be put in motion again before the operation can be resumed: this is a heavy additional load upon the first mover, and has another more serious evil in straining the pipe and all parts of the machinery; because the column of water in the pipe, after it stops, runs back for a small space until the valve shuts; and it makes just as great a concussion or shock when its motion is suddenly stopped by the shutting of the valve, as any other solid body would do which was of the same weight, and moved with the same velocity. In large steam-engines, the shock occasioned by the shutting of the valve is exceedingly violent, unless an air-vessel is applied. In that case, if the pump urges the water with a sudden motion, the air in the vessel will yield, and admit the water into the vessel in far less time than the whole column of water could be urged into motion; but as the air will become compressed by more force than the column of water in the pipe, the elasticity of the air will force the water from the vessel and up the pipe with a regular motion, and this will continue until the air has regained so much space that its elasticity is only just sufficient to balance the column of water in the pipe.

The air-vessel should be placed as near the pump as possible, that it may produce an equable motion of the water in the whole length of pipe. The air-vessel is of considerable advantage when a column of water of great length is to be raised by a single-acting pump. If the piston of the pump at one end of the pipe is put at once into motion, even with a moderate velocity, the strain on the pipe would be very great before the column of water could be put in motion. But the air-vessel tends to make the motion along the main-pipe less desultory, and therefore diminishes those strains which would really take place in the pipe. It acts like

like the springs of a travelling carriage, whose jolts are incomparably less than those of a cart, and by this means really enables a given force to propel a greater quantity of water in the same time.

The stream produced by the assistance of an air-vessel is almost perfectly equable, and as much water runs out during the returning of the piston as during its active stroke; but it must not be imagined that it therefore doubles the quantity of water. No more water can run out than what is sent forwards by the piston during its effective stroke. The continued stream is produced only by retaining part of this water in the air-vessel during the stroke of the piston, and by providing a propelling force to act during the piston's return; but it cannot enable the moving force of the piston to produce an increased effect: for the compression which is produced in the air-vessel, more than what is necessary for merely balancing the quiescent column of water, reacts on the piston to resist its compression just as much as the addition of a column of water would do, the height of such column being sufficient to produce the required velocity of the efflux.

Machines for working Pumps.—The best method of working pumps from a first mover which acts with a rotative motion, is by means of cranks; and if two or more pumps are to be actuated by the same machine, the cranks for them should be placed at regular intervals round the centre, so as to produce a continual action.

It has been observed, in our article *STEAM-Engine*, that the reciprocating motion obtained by a crank is very unequal, even when the rotative motion of the crank is quite uniform. This renders the motion of the piston in the barrel of the pump irregular, for at the top and bottom of the barrel the motion of the piston is very slow, but when the piston is at the middle of the barrel the piston moves quickly. This property is a great advantage in working pumps, because it puts the column of water in motion with a less sudden shock; but it has been very generally mistaken and considered as a defect, and many ingenious contrivances have been proposed, by means of racks and pinions, to give an uniform motion to the piston-rods of pumps. These have never succeeded in practice, and have always been laid aside.

The attempts of mechanicians to correct this unequal motion of the piston-rod are misplaced; for if it could be done it would greatly injure the performance of the pump. As this is a favourite speculation, and new attempts to perfect it are constantly making, we think it right to shew the reason of their failure.

Suppose the first mover to move uniformly with a rotatory motion, and that the machinery is so constructed, that the piston-rod will be moved up and down with a regular motion, or that the velocity of the piston shall be at all times the same, whether it is at the top or bottom, or in the middle of its course. In this case, at every reciprocation, the column of water in the main pipe must be suddenly urged into motion from a state of rest, and the machine could not perform one stroke, if the velocity of the first mover did not slacken a little, or if the different parts of the machine did not yield by bending or compression. These strains would be so sudden and violent, that no strength of materials could withstand the violence of the shocks at every reciprocation of the motion. This would be chiefly experienced in great works which are put in motion by a water-wheel, or some other equal power, exerted on a large mass of matter, of which the machine consists. The water-wheel, being of great weight, moves with steadiness or uniformity; and when an additional resistance is opposed to it by the beginning of a new stroke of the piston, its quantity of motion is but little affected by this addition, and it pro-

ceeds with very little loss of motion. The machine must therefore yield a little by bending and compression, or it must break to pieces, which is the common event.

A crank is free from this inconvenience, because it accelerates the piston gradually, and brings it gradually to rest, while the water-wheel moves round with almost perfect uniformity. It has been stated as an inconvenience of this slow motion of the piston at the beginning of its stroke, that the valves do not shut with rapidity, so that some water gets back through them; but this is a mistake, because the valves always fall by their own weight as soon as the water ceases to flow upwards through them. Now when the piston begins to move with its slow motion towards the end of the stroke, less water is caused to flow through the valves, and in consequence they close gradually, and will be fully shut by the time that the piston becomes motionless, and before it begins to return. This is shewn in the large machines, such as that of London-bridge, where the pumps are worked by cranks, and the valves close imperceptibly; but in a steam-engine of the same power, the shock occasioned by the shutting of the valves is exceedingly violent. In short, by a judicious application of the crank and a fly-wheel, or an air-vessel, and by employing two or three barrels to the pump, the evils of the reciprocating motion of pumps may be completely remedied, and on this account we consider, that if a rotatory pump could be brought to perfection, it would have no superiority over an accurate pump with a straight barrel.

Mr. Smeaton's proportions for a two-horse pump machine for raising water are as follow: horse-track thirty feet diameter; great cog-wheel nineteen feet diameter, with 144 cogs; this gave motion to a trundle of seventeen staves, fixed upon an horizontal axis, which carried a cast-iron fly-wheel of ten feet diameter, and the rim three inches by three inches. On the extremity of the horizontal axis was a crank of a foot and a half in length, which, by means of a connecting-rod, gave motion to one end of a working beam or lever of seventeen feet long, which was poised on a centre in the middle of its length, and at the opposite end was an arched sector for the chain, by which the pump-rod was suspended. The pump was a sucking-pump, six inches diameter in the barrel, and the length of the stroke was three feet. A weight was applied to the end of the beam over the crank, which was sufficient to balance one-half of the column of water in the pump. In this machine, when the horses walked two miles and a half *per* hour, they made two turns and one-third *per* minute. The trundle and fly-wheel made twenty turns *per* minute; the pump made the same number of effective strokes, and raised upwards of a hundred barrels ale measure *per* hour. By the counter balance and the fly-wheel, the resistance to the horses was rendered perfectly uniform.

The *Pump Machine at Blenheim*, which was erected by Mr. Aldersa for the duke of Marlborough, is thus described by Mr. Ferguson in his lectures. The water-wheel is undershot, and is turned by the fall of the water running down an inclined plane, and striking the floats of the wheel. The extremity of the pivot or gudgeon is formed into any number of cranks; for instance six, that is, three at each end of the axis, more or less, according to the force of the fall of water, and the height to which the water is intended to be raised by the engine. As the water-wheel turns round, these cranks move as many levers up and down, by the iron connecting-rods. These levers alternately raise and depress the pistons of the forcing-pumps by other iron rods, which are attached to the opposite ends of the levers, and as one is raised the opposite piston is depressed. Pipes go from all these pumps, to convey the water which they draw up (to a small height) into a close cistern or box, from which

devoted to the water-machines, that is, five on the London side, and one on the Southwark side.

Mr. Smeaton's great Engine at the fifth Arch of London Bridge.—This machine is represented in perspective, in Plate II. WATER-WORKS, *Machines for raising Water.* The view being taken from beneath the arch of the bridge, BB represents the starling of the fourth pier of the bridge, composed of a vast body of piles driven into the bed of the river, and the interstices filled up with chalk and gravel. Upon the heads of these piles, a set of horizontal beams are laid in the manner of joists, and all is made level by chalk and gravel.

The fifth pier CC is made in the same manner. The water-wheel FFGG is made of such a breadth as to fill the space between the two starlings as exactly as possible, without touching; and the bearings for the gudgeons of its axis are supported upon head-stocks EE, which rest upon the starlings. The water-wheel has four circular rings FFFF, each sustained by six arms mortised into the axis; each ring has twenty-four stars mortised into it, and to these are nailed the float-boards ff, upon which the water acts to turn the wheel round.

Upon each end of the main axis is fixed a large wooden wheel HH, round which cast-iron rings of cogs are fixed in segments. These cog-wheels turn two trundles, which give motion to the forcing-pumps, which are six in number, viz. one three-barrelled pump on each side of the water-wheel; but only one of the engines or triple pumps is shewn in the figure, for as the other is exactly the same, it is sufficient to describe one. The axis on which the trundle I is fixed is of cast-iron; it is connected with a triple crank, one arm of which is marked b, and two others are hidden behind the frame: ghi are strong iron rods, joined to the cranks at their lower ends, and to the ends of the great levers or regulators KLM at the upper ends.

The regulators are poised on centres in the middle of their length, and have arches klm at the other ends, which are struck from the centres of motion, upon which arches the chains are laid, to give motion to the piston-rods of the pumps N.

By the motion of the water striking the float-boards, the water-wheel is made to revolve on its axis, and the large cog-wheel H with it. This turns the trundle I and the triple cranks bc, which, being arranged round the axis at equal intervals, elevate and depress the crank-rods ghi and regulators KLM successively, and give to the pump-rods and pistons a vertical motion.

The joints of the crank-rods ghi are made to screw together round the crank-neck with brasses between; by this means they work very pleasantly, and when worn can be screwed up tight again that they may have no shake. The crank-rods are each made in two lengths, each of which has a flanch at the end, and they join at n in the middle of the rod: the flanches are held together by three screws, so as they may be taken apart occasionally without difficulty, when the pump-forcers are to be drawn out of the barrels to new leather them.

The joints at the end of the beam or levers are made with brasses, and screws to adjust them; and so are the centres or fulcrums of the levers.

The levers or regulators are admirably well designed to be strong, with but little timber; they are formed of two pieces of timber, between which the cast-iron axis on which they turn are placed; and then the ends of these pieces are bent to touch, and are kept together by hoops and screw-bolts, so as to make close joints. At the ends, several small square pieces of wood are interposed cross ways in these

joints at the ends of the lever, being let into both timbers; by these, when they are firmly bound together, the two pieces of timber are prevented from sliding end ways upon each other, so as they form an excellent truss-beam, for it cannot bend or yield without stretching one timber and compressing the other.

The pump-rods are attached to the arches at the ends of the beams by four iron chains each, as is shewn in fig. 2. The rod has a cross-piece p fixed on the top of it, to which the two outside chains are attached, and the lower ends of the same chains are fastened at the lower end of the arch.

These chains act to pull down the piston-rods; the other two chains which return or raise the rods are fastened to the top of the arch, and to the rods at the lower ends, as shewn in the figure.

The pumps are forcing-pumps, and raise the water when the pistons are depressed: the lower piece of the triple pump is a square iron-pipe or trunk, screwed fast down upon the groundfells of the engine-frame; this is called the suction-piece: it has a flanch at each end, to one of which a lid is screwed, and the other joins it to the suction-pipe R, which brings up the water from the river. On the top of the trunk, the three barrels N are screwed, each having a valve in the joint, which allows water to enter into the barrel, but prevents its return. From the bottom part of each barrel proceeds a crooked pipe q, which communicates with another square trunk S, called the forcing-piece, having valves at the joint, to prevent any water from getting back into the barrels. On the top of the trunk over each valve is a round hole, over which a lid is screwed, but can be removed to clean or repair the valves when necessary. Similar lids are screwed on over openings into the suction-trunk, at the back towards the cranks. At the ends of the forcing-trunk S are flanches, one of which receives a lid like the lower trunk, and the other flanch joins to the pipe s, which conveys the water away from the pumps.

The pistons or buckets of the pumps are solid, that is, without valves in them; and their action is as follows:

When the piston of any of the barrels is drawn up, it makes a vacuum in that barrel; and the pressure of the atmosphere on the surface of the water from which the suction-pipe R draws, raises the valve at the bottom of that barrel, and fills it with water. At the descent of the piston, the lower valve shuts, and the water contained in the barrel can find no passage but through the valve in the forcing-trunk S; and when the piston is drawn up again this valve closes, and the lower one opens to give a fresh supply of water to the barrel. By the position of the triple cranks, it always happens that one or other of the barrels is forcing the water into the force-pipes; and as the strokes of the other set of pumps at the other end of the water-wheel are contrived to be intermediate or alternating to these, a constant succession is kept up.

The main-pipe s is continued to the shore, to convey the water into the streets. A wooden cistern T is placed over the pumps to hold water, and keep a constant supply of it above the pistons to prevent leakage. The whole engine is surrounded by a strong timber fence, which guards it from the injuries it might receive from vessels or floating ice, striking it at high water, when the water rises above the level of the starlings nearly to the axis of the water-wheel. On the tops of these piles, a large stage is built, to serve as a road from the shore to the engine, and the under-side of it supports the main-pipes, which convey the water ashore. There are also other stages in different parts of the machine, to support workmen when repairing it; these prevent the whole engine from being seen from the bridge at one view, and for

for this reason they are omitted in the drawing, which is in some degree imaginary, as it represents the engine detached.

This machine is more simple than the preceding, as it performs more work by six pumps of ten inches bore and $4\frac{1}{2}$ feet stroke than the other by sixteen pumps of seven inches bore and $2\frac{1}{2}$ feet stroke, and therefore with much less loss of power by friction; and as the cranks only work in one direction, they work much more pleasantly than when there are pumps at both ends of each lever, because in that case the strain on the cranks, connecting-rods, and the fulcrums of the levers, in fact on all the joints, is alternately in different directions, and if there is any shake or looseness in the joints, it produces jerks and irregularities. By using three barrels and triple cranks, the supply of water, forced into the main-pipe, is more equable than when four are used, though not perfectly so. The perpendicular motion produced by the arches and chains, is a great advantage in making the barrels wear equally.

In order to enable this engine to work as long as possible in each tide, and after the velocity of the motive water is abated, it is contrived to adjust the resistance to the diminished power. This is done in the most simple manner by a small cock and pipe in the chamber of each pump-barrel; just above the suction-valve from this cock, a rod of communication rises up to the stage to turn it by, and this cock being opened will admit air into the barrel when the piston is drawn up, so that the water of the river will not be drawn up into that barrel; and in consequence, it will become inactive, and the wheel will be relieved from the load of working it. In this way, the load of the engine is adapted to the power of the tide at its different periods; but when all the three barrels are thus relieved by opening the air-cocks, the motion of that engine becomes a useless loud friction of the pistons and movements; and to relieve this, the shaft or axis of connection between the axis of the trundle and the triple crank, is provided with the means of disuniting or uniting them whilst in motion, so that one engine will stand still whilst the other is at work.

The principal dimensions of this machine are as follow:—The water-wheel is thirty-two feet diameter, measuring to the outside of the float-boards; the length of the float-boards fifteen feet and a half, and their breadth four feet and a half; the number of float-boards twenty-four. At each end of the axis is fixed a cog-wheel, fourteen feet diameter, with eighty cogs: each of these turns a trundle of twenty-three staves, fixed on the axis of the cranks, which are triple; that is, three cranks are formed side by side on the same axis, and bent in different directions, so as to produce a continual action. Each crank actuates a lever or working beam eighteen feet long, which is poised on a fulcrum in the middle, and gives motion to the pump-rods by an arch-head and iron chains. The pump-barrels are ten inches diameter, and the pistons make strokes of four feet and a half long; they are forcing-pumps, and three barrels are combined together, to throw the water into one main pipe, which conveys the water into the town; the highest elevation to which the water is ever lifted is a hundred and twenty feet. The cranks, beams, and pumps, at each side of the wheel, are exactly similar, so that the wheel actuates six pumps.

This machine was erected, under Mr. Smeaton's directions, in 1767, and worked constantly for fifty years, when the timber-work becoming decayed, it was rebuilt in 1817, with cast-iron instead of wood, and has been lately set to work. The principal proportions of Mr. Smeaton's design have been preserved, but the great levers have been suppressed, and the cranks are placed over the same pumps as the former.

Mr. Smeaton's Pump Machine at Stratford Water-works.—This is so like the last, that we shall only give the principal dimensions, as an example of the best proportions for a machine with a breast-wheel, the last being undershot. The water-wheel was sixteen feet diameter and eight feet wide; upon its axis was a cog-wheel of eleven feet and a half diameter, with seventy-eight cogs, which turned a cog-wheel of five feet one inch diameter, with thirty-five cogs. This was fixed upon the axis of the cranks, which were three in number, and by means of three beams gave motion to three forcing-pumps nine inches diameter and two feet and a half length of stroke, lift of the water 84 feet. In addition to the pair of cog-wheels just mentioned, there was another pair, of different proportions, fixed close to the sides of the others, and by a simple contrivance either pair could be brought into action, and the other pair would then be disengaged. The second wheel, which was fixed in the axis of the water-wheel, was nine feet eight inches diameter, with sixty-six cogs, and the wheel on the axis of the cranks which belonged to it had forty-seven cogs. The intention of these two sets of wheels was to adapt the water-wheel to work equally well when it was flooded and impeded in its motion, as when the water was low; for when the quick motion was in use, the cranks made 15.6 revolutions *per* minute, whilst the water-wheel made seven revolutions. But when the slow motion was in use, the cranks would make $15\frac{1}{2}$ revolution *per* minute, whilst the water-wheel made eleven. This machine is seven horses' power.

The *Pump Machine at Marly*, near Paris, being so much celebrated on account of its magnitude and the multiplicity of its parts, we shall be expected here to give some account of it, which we have taken from Belidor, and we shall subjoin a few remarks upon its construction, from which it will appear we do not recommend it as a model.

This machine is situated between Marly and the village La Chauffée. In that place the river Seine is penned up partly by the machine and partly by a dam, which keeps up the water; but in order that the navigation may not be interrupted, a canal has been cut, two leagues above Marly, for the passage of boats and barges. There has been erected, about thirty-five fathoms from the machine, a contrivance, called an *ice-breaker*, to prevent floating pieces of ice or timber, which come down the stream, from damaging the machine, and the better to secure the pen-flocks, and the channels in which the water-wheels move. There is a grate of timber to stop whatever may come through the ice-breaker.

The water is raised to its destined height by the force of fourteen undershot water-wheels, which work the pumps at three different stages: first, one set of pumps to lift the water from the river, to a reservoir placed up the hill two hundred and thirteen yards from the river, and at the elevation of a hundred and sixty English feet above the level of the Seine. The power of the wheels is conveyed also to this place by chains, in order to work a second set of pumps, which force the water to the second reservoir, a hundred and eighty-six feet higher, and therefore three hundred and forty-six feet above the river, and six hundred and ninety yards distant. At this spot is a third set of pumps, to throw up the water from the latter to the summit of a tower a hundred and eighty-nine feet higher, and at a distance of one thousand three hundred and thirty yards from the river up the mountain. The whole elevation is rather more than five hundred and thirty-five feet above the river. From the cistern in the tower the water is conveyed, by an immense aqueduct, to the gardens of Marly.

The breadth of the machine comprehends fourteen water-courses,

courses, each shut by a sluice or pen-stock, which can be raised and depressed by racks, and in each of these courses an undershot wheel is placed. The fourteen wheels are disposed in three lines across the river. In the first line, which is up the stream, there are seven wheels, in the second line six, and only one in the third.

The wheels are thirty feet diameter, and five feet wide, and they are all nearly the same as follow: the ends of the axle of each wheel go beyond their bearing pieces, and are bent into cranks, which make levers of two feet; the crank which is towards the mountain gives motion to a beam or lever, which carries four pistons or forcers at each end, to work in the barrels of as many forcing-pumps, which as the wheel works alternately suck up the water of the river, and drive it up into the first cistern. The other crank at the opposite end of the axle gives motion to the chains, which go up the hill, to work the pumps in the two elevated cisterns.

Each of the six wheels on the first line is constructed in this manner, to give motion by one of its cranks to an engine, consisting of eight forcing-pumps combined together. The engine is actuated by a lever or beam, from each end of which a square piece of wood is suspended, that carries and directs four pistons of forcing-pumps; the beam of the engine is put in motion from the crank of the wheel by a beam or leader, which is connected with the crank of the wheel at one end, and with one arm of a regulator or bent lever, whilst the other arm of this regulator is united by another leader to the extremity of the beam of the engine, which beam is thus made to vibrate up and down and work the pumps.

Of the six wheels we have just mentioned, there are five which, by their opposite cranks, give motion to the pumps in the elevated cistern of the first lift. This is effected by means of one vertical beam or lever, and two horizontal levers, which are bent, and actuate the chains that communicate the motion; the three levers are only to change the direction of the motion of the crank into a proper direction to go up the hill. The sixth wheel, which is the first towards the dam, gives motion to a long chain that goes up the hill to work the pumps of the upper cistern. The seventh wheel of the first line is exclusively applied to move a chain, which goes to the first cistern, by both its cranks.

The six wheels of the second line are like the five wheels in the first row, *i. e.* one of the cranks of each works an engine of eight pumps, and the other a chain that goes to the upper cistern.

Lastly, the single water-wheel, which is on the third line by each of its cranks, works an engine of eight forcing-pumps fixed in the river, and of itself supplies one conduit-pipe of eight inches and a half bore.

There are then eight engines in the river, and reckoning all the chains which go up the hill, they are thirteen in number, including the chains that come from the sixth and seventh wheels of the first line: these thirteen chains ascend the hill all together, and are suspended at regular intervals of twenty feet by levers, to bear them up from touching the ground, which by moving on their centre admit of the working of the chains. Each chain is double, that is, there is a second chain, which is connected to the opposite ends of the suspending levers, and each chain serves to draw the other chain back again after it has made its stroke. Five of these double chains are employed to actuate levers, which work thirty inverted lift-pumps situated in a cistern at the first lift, and which drive the water through two pipes of eight and a half inches bore up to the upper lift. The

other eight double chains go straight on to the upper cistern.

The seven chains of the wheels of the first line, in going along, work also eight sucking-pumps, placed a little below the cistern of the first lift, because in that place the water of a considerable spring is brought by an aqueduct, and these same chains take up that water a second time by forty-nine pumps, which are situated in a separate cistern, at the first lift, on a level with the first cistern, and force it into the upper reservoir, through two conduit-pipes of eight and a half inches diameter, and three others of six and a half inches diameter.

The water raised by the seventy-nine pumps in these two cisterns at the first lift, discharges itself into a great reservoir at the second lift, and thence by two conduit-pipes of a foot diameter each, it runs into reservoirs of communication, and is distributed into the several wells or little pump-cisterns of the upper cistern, which all together contain eighty-two inverted lift-pumps; these force the water through six conduit-pipes of eight inches and a half diameter up into the cistern, in the tower which answers to the aqueduct. These eighty-two lift-pumps are worked by the eight great chains before mentioned, that go straight to the upper cistern, without moving any pumps by the way; and the same chains work sixteen sucking-pumps behind the upper cistern, to bring back into the reservoir of the same cistern the water which leaks out of the six iron pipes that go to the tower.

To sum up all the pumps of this intricate machine:

1. The eight engines in the river contain sixty-four pumps, which suck and force the water 160 feet up five iron pipes of eight and a half inches bore, and 213 yards long, up to the first lift.

2. The two cisterns at the first lift contain seventy-nine lifting-pumps, which raise the water 186 feet, through four pipes of eight and a half inches bore, and three pipes of six and a half bore, and 477 yards up to the second lift.

3. The cisterns at the second lift contain eighty-two lifting-pumps, which raise the water 189 feet through six pipes of eight and a half inches bore, distance 640 yards: In all 225 forcing-pumps, which lift 535 feet and 1330 yards distance. To this must be added eight sucking-pumps in the river called feeders, which raise water into the cisterns at the top of the forcing-pumps, to keep water in the pumps, and prevent leakage; also the eight others which are below the midway cistern; and lastly, the sixteen sucking-pumps, which we mentioned as placed behind the upper cistern, so that the machine has in all 257 pumps.

The basin of the tower, which receives the water raised from the river, and supplies the aqueduct, is 1330 yards distant from the river, and 535 feet above the level: the water having run along a stone aqueduct, which is raised upon thirty-six arches, is separated into different conduits, which lead it to immense reservoirs at Marly, and formerly conveyed it also to Versailles and Trianon.

Such is the mechanism of the machine of Marly. Its mean produce in Belidor's time was from 3000 to 4000 English cubic feet of water *per* hour: he says mean produce, because under certain favourable circumstances it has formerly raised more than 8484 cubic feet *per* hour. But during inundations, or when the Seine is frozen, when the water is very low, or when any repairs are making, the machine stops in a great measure, if not entirely.

The annual expences of the machine have been stated formerly at 3300*l.* sterling, or 9*l.* *per* day, including the salaries of those who superintend it, and the wages of the workmen employed, together with repairs, necessary articles, &c. This makes about one farthing for every eleven cubic

cubic feet. Or, taking into the account the interest of 333,000*l.*, the original expenſe of erection, which is five times as great as the annual expenſe, 11 cubic feet, which is 67 gallons, will coſt three half-pence, or at the rate of a farthing for 11 gallons.

This is the account of it given by Belidor in his ſecond volume.

Rannequin, the inventor, was an ingenious practical mechanic, but no mathematician or philoſopher. In ſeveral poſitions, the moving forces act unneceſſarily obliquely, which occaſions a great loſs of power, and renders the machine leſs effectual. A great proportion of the whole moving power of ſome of the water-wheels is employed in giving a reciprocating motion to the ſets of rods and chains, which extend from the wheels to the ciſtern, nearly two-fifths of a mile diſtant, where they work a ſet of pumps.

As this machine is continually quoted as the moſt powerful of all machines, we will compare its power with ſome of the large ſteam-engines in England. The quantity of water is $(8484 \div 60 =)$ 141 cubic feet *per minute* \times by 535 feet, the height to which it is raiſed, = 75649 cubic feet *per minute* liſted one foot high. Divide this by 528 cubic feet, which is the quantity that can be liſted one foot *per minute*, by what is called a horſe-power in ſteam-engines = 143 horſe-power; but as the machine acts by 14 water-wheels, each one will be ſcarcely $10\frac{1}{2}$ horſe-power. The horſe-power is one-third greater than the average of horſes, and we therefore eſtimate that 215 horſes working together, would do as much work as this machine ever did, or 15 horſes to each wheel; but as the horſes could only work eight hours *per day*, three ſets muſt be kept to continue conſtantly.

M. Montgolfier informs us that the ſupply of water to the wheels is 138000 cubic feet *per minute*, and the fall is $4\frac{1}{2}$ feet; this gives a power $8\frac{3}{4}$ times as great as the effect produced. Montgolfier found $22\frac{1}{2}$ times when he tried it.

The whole work is now in a very ruinous ſtate, and many projects have been formed for a reſtoration of the machine on better principles.

It is probable Rannequin thought his moving force would not be ſufficient to raiſe the water to the height of 535 feet at once; and this is agreeable to the practice of more modern engineers.

If the machinery was conſtructed in caſt iron, in the ſame manner as ſteam-engines are now made, the force of one crank would be more than ſufficient to raiſe a cylinder of water of that altitude, and above eight inches in diameter, without any complication; but the pipes would require very great ſtrength. This is proved by a machine that has been lately erected at Marly, in place of one of the old water-wheels.

Even according to the original conſtruction, the water might be raiſed in one jet to the ſecond reſervoir. This appears from two experiments, one made in 1738, and the other in 1775. In the firſt, M. Camus endeavoured to make the water riſe in one jet to the tower; his attempt was not attended with ſucceſs, but he made the water riſe to the foot of the tower, which is conſiderably higher than the ſecond reſervoir. During this experiment the machine was ſo much ſtrained, that it was found neceſſary to ſecure ſome parts of it with chains.

The object of the ſecond trial, made in 1775, was to raiſe the water at once to the ſecond liſt, 346 feet. It did aſcend thither at different times, and in great plenty, but the pipes were exceedingly ſtrained at the bottom, ſo that ſeveral of them burſt, and it was neceſſary to ſuſpend

and recommence the experiment ſeveral times. This aroſe from a fault which might eaſily have been remedied; *viz.* from the age of the tubes and their want of ſtrength; therefore it reſults from this trial, that the chains which proceed from the river to the firſt liſt might be ſuppreſſed, together with the firſt well itſelf: and this perhaps is all that is to be expected without a complete change in the machinery.

Rules for calculating the Dimenſions of Pumps.—The quantity of water delivered by any pump will be in the joint proportion of the ſurface or baſe of the piſton and its velocity; for this meaſures the capacity of that part of the working barrel which the piſton paſſes through; and the ſame is true of ſector pumps, or rotative pumps: but as pumps with ſtraight cylindrical barrels are the only kind in general uſe, it will be ſufficient to give the rule for calculating the content of a cylinder, which is ſimply to multiply the area of the baſe by the length; thus, take the diameter of the barrel in inches, and the length of the ſtroke in feet.

Square the diameter in inches, and divide by 183.3: multiply this by the length of the ſtroke in feet, and it gives the content of the cylinder in cubic feet.

Example.—How many cubic feet of water will be raiſed in an hour by a pump $8\frac{1}{2}$ inches diameter, and $3\frac{1}{2}$ feet ſtroke, which makes 18 ſtrokes *per minute*?

Diameter 8.5 inches \times 8.5 = 72.25 circular inches: divide it by 183.3, which is the number of circular inches in a ſquare foot, and it gives .394 ſquare feet for the area of the barrel \times 3.5 feet in length = 1.379 cubic feet; the content of the barrel \times 18 ſtrokes *per minute* = 24.822 cubic feet of water raiſed *per minute* \times 60 minutes = 1489 cubic feet *per hour*.

If it is required to know the quantity which a pump will raiſe in ale gallons, it is obtained by the following rule: take the diameter of the barrel in inches, and the length of the ſtroke in feet.

Square the diameter in inches; multiply by the length in feet, and divide by 30.

This ſhould give the content of the barrel in ale gallons of 282 cubic inches each; but the rule is not perfectly correct, for it aſſumes the gallon to be $282\frac{3}{4}$.

Example of the ſame Pump as above.—The ſquare of the diameter is 72.25×3.5 feet in length = 252.875 \div 30 = 8.429 ale gallons for the content of the barrel. The true meaſure in this caſe is 8.45 gallons, which is very near.

To find the force requiſite to work any pump, take the diameter of the barrel in inches, and the perpendicular height of the column of water in feet.

Square the diameter in inches; multiply by .34 decimal, and multiply by the height of the column in feet.

This gives the force in pounds avoirdupois. It is uſual to add one-fifth to this weight, on account of friction and reſiſtance.

Example.—Suppoſe the above pump liſts the water 64 feet in the whole, what force will it take to draw up the piſton?

The ſquare of the diameter is $72.25 \times .34$ lbs. = 24.565 lbs., which is the weight of one foot high of the column \times 64 feet = 1572 lbs., the weight of the whole column. Add $\frac{1}{5}$ th of this, *viz.* 314 lbs. = 1886 lbs. the weight required to draw up the piſton and give it a proper velocity.

In conſtructing pumps, care muſt be taken to avoid all unneceſſary contractions in the valves or pipes which convey the water. If the water-way is too ſmall, the water will

WATER.

be greatly resisted in its passage through such contractions; and this is called by the workmen wire-drawing the water.

The velocity of the water in the conduit-pipe, and in its passage through every valve, will be greater or less than the velocity of the piston, in the same proportion that the area of the piston or working barrel is greater or less than the area of the passage of the valve. For whatever quantity of water passes through any section of the working barrel in a second, the same quantity must go through any one of the passages: this enables us to modify the velocity of the water as we please, and we can increase it to any degree at the place of delivery, by diminishing the aperture through which it passes, provided we apply sufficient force to the piston. This is the case in the engine for extinguishing fires; but no such increase of velocity must be suffered in pumps which are required to raise the greatest quantity of water with a given power; because the power required to force the water with a great velocity is very considerable, and the velocity so obtained adds nothing to the mechanical effect which is produced. The resistance arises from a two-fold cause; *viz.* the friction of the water against the sides of the passage, and still more from the resistance which water opposes to any sudden change of figure; for though water is a perfect fluid, and will readily accommodate itself to any change of figure by its own gravity, yet, it requires some time to make such change; and if we force it to change its figure in less time than it naturally would, it requires mechanical power to do so, just the same as to

compress a mass of clay, or other soft and non-elastic body.

In practice, the velocity with which the piston of the pump moves, determines the size of the smallest passage through which the water can pass without unnecessary resistance. Few pumps move with a greater velocity than 80 or 100 feet *per* minute; and we think the area of the narrowest passages and pipes should bear such a proportion to the area of the barrel, that the water will never be urged with a greater velocity than three feet *per* second, or 180 feet *per* minute, if the power required to move the pump is an object. In general, this will be accomplished by making the area of the smallest opening equal to half the area of the barrel; or if the diameter of the barrel is divided into 10 parts, the diameter of the least opening should be 7 of those parts. If the pump moves slower, then the passages may bear a smaller proportion. The pumps which have solid pistons are preferable, because the valves can be made of any size which is desired; but when a valve is made in the piston, its size is necessarily limited to less than we have recommended.

Estimate of the Strength of Men to raise Water.—Various authors have stated the mean force of a man so widely different, that the student is perplexed which to choose. The following table contains several of these statements, which we have reduced to one common denomination; *viz.* the number of pounds avoirdupois, or the number of cubic feet of water which a man can raise up in one minute to the height of one foot.

Authors.	Pounds Avoirdupois raised one Foot <i>per</i> Minute.	Cubic Feet of Water raised one Foot <i>per</i> Minute.	Duration of the Work.
Hachette - - - -	1343	21.5	Working 10 hours <i>per</i> day.
Amontons - - - -	1530	24.48	
Euler - - - -	3000	48.	
Smeaton - - - -	{ 3668 3750 3859	{ 58.7 60. 61.7	Working during 8 hours in 24.
Bernouilli - - - -	4144	66.3	
Schulze - - - -	4410	70.5	For 8 hours.
Defaguliers - - - -	5500	89.6	For 10 hours.
Emerfon - - - -	6300	100.8	
Dr. Robinfon - - - -	{ 5031 6648	{ 80.5 106.4	{ A feeble old man, working 8 or 10 hours <i>per</i> day, a pump without friction. { A young man weighing 135 lbs.: 10 hours <i>per</i> day.
Average of all these - - - -	4098	65.5	
True standard - - - -	3750	60.	Working 10 hours <i>per</i> day.

It is not difficult to account for these great differences, when we consider how the muscular force varies in different individuals, and also the power of enduring fatigue. The only means of ascertaining the mean force of a man is to take the sum total of the work executed by a number of men acting for a great length of time. This was repeatedly done by Mr. Smeaton, on a very large scale, and with so very little variation, that we can very confidently recommend engineers to calculate a man's force at 60 cubic feet, or 3750 lbs., raised one foot *per* minute: as this is just one cubic foot *per* second, it will easily be fixed in the memory. Defaguliers' estimate of one hoghead raised ten feet high *per*

minute, is very frequently used, and is 5500 lbs. raised one foot *per* minute, but it is too great for a man; and Defaguliers himself called it the maximum, which no machine can exceed.

When a machine is to be turned by the force of a man turning a winch or handle, the handle ought not to be longer than from 12 to 16 inches; nor should it be calculated to make more than 30 turns *per* minute; and when moving with this velocity, it should not require a greater force than $16\frac{2}{3}$ lbs. pressure upon the handle; or a man will not be able to move it without greater fatigue than he can endure for a day's work. If the handle is required to move slower,

WATER.

slower, for instance 20 turns *per* minute, then the load may be increased in proportion; *viz.* to 25½ lbs., and this will be less fatiguing.

The Force of Horses to raise Water.—This we find as variously stated by different authors as the force of men.

Authors.	Pounds Avoirdupois raised one Foot <i>per</i> Minute.	Cubic Feet of Water raised one Foot <i>per</i> Minute.	Duration of the Work.
Hachette's estimate that a horse is equal to 7 men - - - - - }	9406	150.5	Working 9 hours <i>per</i> day.
Fenwick - - - - - }	13200	211.2	
Gregory - - - - - }	18480	295.6	
More - - - - - }	21120	337.9	
Watt - - - - - }	20000	320.0	
Smeaton's 2 horse machine, with an Archimedes' screw - - - - - }	20104	321.6	Working 9 hours <i>per</i> day, light work.
Smeaton's 4 horse machine to work a flash-wheel - - - - - }	20418	326.7	Working 8 hours <i>per</i> day.
Smeaton's standard - - - - - }	22916	366.6	
Defaguliers' estimate that a horse is equal to 5 men - - - - - }	27500	440.0	{ Working 4½ hours <i>per</i> day, 4 horses were kept in order to work for 9 hours <i>per</i> day. { The strongest horses, such as are used in London, cannot work at this rate throughout the day.
Smeaton's experiment on drawing coals with 2 horses - - - - - }	27720	443.0	
Messrs. Boulton and Watt's horse-power in steam-engines - - - - - }	32000 33000	512.0 528.0	
True standard - - - - - }	22000	352	{ Working 8 hours <i>per</i> day, nearly equal to 6 men.

In this, as in the former instance, we feel inclined to give the preference to Mr. Smeaton's estimate, both from his superior experience and accuracy, and also because by his MS. papers, we are informed of the particulars of his experiments. He found, from examining the accounts of a colliery, that each horse drew 27720 pounds one foot *per* minute; but as they could only continue to work at that rate for 4½ hours *per* day, Mr. Smeaton fixed his standard at 250 hogheads *per* hour raised ten feet, which is equal to 22,916 pounds, raised one foot high. Still we find in two of his machines, of which we have already given the particulars, the performance fell rather short; we have, therefore, chosen to recommend 352 cubic feet of water, or 22,000 pounds *per* minute raised one foot high, as a standard for a horse's force, when he works 8 hours *per* day, and moves with a velocity of 2½ miles *per* hour. This is settled by universal consent as the most proper pace for a horse to walk; and he will in that case draw just 100 pounds, which is an easy number to remember.

The estimate of Defaguliers we consider as the maximum of a horse's power; for the horse-power of Messrs. Boulton and Watt is only used as a measure of the force of their *steam-engines*. See that article.

In applying horses to work machines, the circular tract in which they walk should be as large as possible, that the horses may turn round in the circle with little inconvenience. Few cases will admit of a walk of more than 30 feet diameter; and in proportion as this is diminished, the horse loses some of his power. No horse-walk should be made of less than 20 feet diameter, if he is required to act with any considerable force. When this size cannot be obtained, we are of opinion that the horse would work to a greater advantage by walking within a large perpendicular wheel, like those wheels used for cranes.

It must be remembered, that the horse should always move with a velocity of 2½ miles *per* hour, or 220 feet *per* minute; and, therefore, the number of turns which he will make in a minute must be proportioned to the size of the track in which he works.

Diameter of the Horse's Track.	Circumference.	Number of Turns <i>per</i> Minute, when the Horse walks 2½ Miles <i>per</i> Hour.
30 feet.	94 feet.	2.34
28	88	2.5
26	81.5	2.7
24	75.2	2.9
22	69	3.17
20	62.6	3.5

The machine which is to raise the water should be so connected with the principal wheel which the horse turns, that it will move with the proper velocity, when the horse-wheel turns at the rate above specified. The velocity proper for most machines is mentioned in the description of each.

Water-Wheels applied to raise Water.—The circumference of a water-wheel will work to the greatest advantage, when it moves with a velocity of from 3 to 4 feet *per* second, or from 180 to 240 feet *per* minute. A very proper velocity for a water-wheel is to make it the same as the horses, by the above table; and we have, therefore, added the velocities for smaller diameters.

Diameter.	Circumference.	Turns per Minute.
18 feet.	56.4 feet.	3.9
16	50	4.4
14	44	5
12	37.5	5.86
10	31.4	7

Few machines, with pumps worked by a water-wheel, will raise more water to a given height in any time, than amounts to one-third the mechanical effect of the quantity of water employed to work it; that is, considering the differences of the heights to which the water is raised, and the height of the fall, and reducing them both to an equality, the quantity of water raised will never exceed half of the

quantity which falls. The other half is lost in friction and leakage, and in overcoming the *inertia* of the parts of the machine.

Pressure engines are those machines which give motion to the piston of a pump, by the force of a column of water acting in a cylinder or barrel, similar to that of the pump. (See the article *PRESSURE-Engine*.) It was omitted in that article, that M. Belidor invented a machine, which may be considered as the first which was perfect, and was indeed the model for that made by Mr. Smeaton. See *Architecture Hydraulique*, vol. ii. p. 240.

M. Baillet made observations upon several machines of this kind in the mines of Hungary, from which it appears that the mechanical effect produced, is only four-tenths of the mechanical effect of the first power.

The French metre is equal to 3.281 English feet, and the cubic metre is 35.3198 cubic feet English.

Power of the largest Steam-Engines to raise Water.—The most powerful machine in existence is the steam-engine, on Mr. Watt's principle, called Stoddart's engine, at the United Mine in Cornwall. Three other engines of equal dimensions are employed to drain the mine, but only this one is loaded so as to exert its utmost force. The steam cylinder is 63 inches diameter, and acts double; that is, it operates to raise water equally in the ascent or descent of the piston. The weight of water in the pumps is 82,000 pounds, and with this load it makes $6\frac{1}{2}$ double strokes per minute of $7\frac{3}{4}$ feet each; or, it gives to the load $100\frac{3}{4}$ feet motion per minute.

Multiply 82,000 pounds by $100\frac{3}{4}$ feet, and it gives 8,261,500 pounds per minute lifted one foot high: divide this by 33,000 pounds, which is called the horse-power, and it gives 250 $\frac{1}{2}$ horse-power for the acting force of the engine. Again, divide 8,261,500 pounds by $62\frac{1}{2}$ pounds, the weight of a cubic foot of water, and we find this engine is capable of raising 132,184 cubic feet of water per minute to a height of one foot. This is not one of the best engines with respect to fuel, and it burns $31\frac{1}{2}$ pounds of coal to raise this quantity.

The whole power employed to drain the United Mine is as follows:

	Horse-Power.
Stoddart's engine, 63 inch cylinder, double acting	250 $\frac{1}{2}$
William's engine, 65 inch cylinder, do.	200
Sim's engine, 63 inch cylinder, do.	185
Poldorey's engine, 63 inch cylinder, do.	196
Total	<u>831$\frac{1}{2}$</u>

Here we have a single machine of nearly double the power of the famous machine at Marly, which is in fact composed of fourteen machines, working in concert for a common object; and so do the four engines in the mine, which amount to $831\frac{1}{2}$ horse-power, without reckoning the engines employed to draw up the ore.

The engines at several other mines in Cornwall are of immense power. We will state two.

The mine called Wheal Alfred has four engines: a 63 inch double engine, which is lightly loaded, and only exerts 80 horse-power; a single acting engine of 66 inch, and 60 horse-power; and two others of 64 and 60 inch, equal to 51 and 54 horse-power:—in the whole, 245 horse-power to drain one mine.

The Dolcoath mine has three engines: a double engine of 63 inch cylinder, and 132 horse-power; a single engine of 63 inch, and 45 horse-power; and a smaller single engine of 20 horse-power:—in all, 197 horse-power to drain the mine.

It will be observed above, that the power of the different engines is not in proportion to the dimensions of the cylinders: this is because the pressure upon each square inch of the piston varies in different engines from 7 to 20 pounds. But custom has established, that certain sizes of cylinders will be equal to a certain number of horses' power, as is shewn by the following table.

The steam in the boiler is supposed to be kept within the limits of from 2 to 4 lbs. pressure on each square inch more than the atmosphere; and in that case the cylinders of the diameters marked in the Table will have very nearly the powers assigned to them.

WATER.

A TABLE of the Dimensions of the Cylinders of the Engines, either Double or Single, showing their different Powers, either to raise Water by Pumps, or to turn Machinery by Cranks and Fly-Wheels.

Nominal Horse-Power.		Dimensions of the Piston.			Effective Pressure or Load on the Piston.		Velocity of the Motion with which the Load is raised.			Mechanical Effect expressed by the Weight which can be raised in a Minute to a Height of one Foot.			Consumption of Coals in an Hour in Pounds Weight.		
Double Engine.	Single Engine.	Diameter in Inches.	Area in square Inches.	Number of square Inches for each Horse-Power.	Pressure on each square Inch in Pounds.	Load on the Piston in Pounds.	Length of the Stroke in Feet.	Number of Strokes per Minute.	Velocity of the Piston per Minute, in Feet.		Cubic Feet of Water.	Pounds Avoidupois.	By Each Horse-Power.	Total.	Single Engines.

This Table is formed from observations of a great number of engines of different powers, and making the intermediate sizes to correspond to the same law of increase. Thus, a twenty-horse engine is always made with a cylinder of 24 inches diameter, which is allowing 22.6 square inches of the piston's surface for each horse-power; but larger engines have a less allowance; an eighty-horse engine has 19.8 square inches to each horse-power, and small engines have a much greater allowance; a ten-horse engine having $24\frac{1}{2}$, and a one-horse, 28 square inches. This difference is to compensate for the numerous disadvantages which always attend small machines.

The proper length of the stroke for different engines is not at all settled. Mr. Watt's first engines were made much longer than this Table, but of late years they have been made shorter, and without any adequate reason which we can perceive; for it must be an advantage to a machine to make as few reciprocations as is consistent with a practicable length of cylinder. These differences in the length of stroke do not affect the calculation of powers, because if the length of the stroke is altered, the number *per* minute is also changed, and the velocity of the piston is the same; at least it will be always nearly the same as the Table for those engines which work a crank and fly-wheel. But it must be observed that these engines move with a greater celerity than the engines for pumping water, because it is necessary to accumulate a considerable velocity in the fly-wheel, or it must be immensely heavy if the piston was to move so slowly as the pumping engine generally does.

It is usual with engine-makers to calculate the velocity of the pistons of engines at 220 feet *per* minute; but we have rarely found them to come up to this in practice, and have therefore calculated them at less. In the Table, the pressure upon each square inch of the surface of the steam-piston is in proportion to the velocities there marked; and if the velocities are found less than the Table, as is the case with engines for pumping, then the load upon each inch of the piston must be increased in proportion, or else the power of the engine will be different, although the cylinder remains the same.

For instance, the engine at the Birmingham canal, mentioned in the article *STEAM-Engine*, had a twenty-inch cylinder; and being a single engine, should, by our Table, be rather more than seven horses power. How does this agree? The weight raised *per* hour to one foot high was calculated, in the article *STEAM-Engine*, at 13,961,805 lbs.; which divided by 60 gives 232,697 lbs. *per* minute: divide this by 33,000, the horse-power, and we have a seven-horse power; so far it agrees with the Table. But the pressure on each square inch of the piston was 11.7 lbs., and the Table says the pressure should be 7.1 lbs. This difference is reconciled by the differences of the velocities; for the piston of the Birmingham engine moved $63\frac{1}{4}$ feet *per* minute, and the velocity in our Table for a single engine is 98 feet: now as 11.7 lbs. is to 7.1 lbs., so is 98 feet to $59\frac{1}{2}$ feet, instead of $63\frac{1}{4}$; the difference is very small, and may be thus accounted for. The Birmingham engine, although seven horses power, had only a twenty-inch cylinder, yet, according to our Table, it should be 20.6; its piston therefore required to move rather quicker, in order to make an equal produce. Thus, the area of a twenty-inch cylinder is 314 square inches; and of a cylinder 20.6 diameter, it is 332 square inches: now as 314 square inches is to 332 square inches, so is $59\frac{1}{2}$ feet *per* minute to 63 feet *per* minute, instead of $63\frac{1}{4}$, which the engine actually moved.

The allowance for fuel in this Table is as small as it will ever be found to be in actual practice; the consumption of

fuel is not in direct proportion to the power of the engine, because small engines lose more heat, and have more friction in proportion than large ones, and the reciprocations of the motion are more frequent. We have taken the effect of the twenty-horse engine at twenty millions of pounds of water *per* minute, raised one foot with each bushel of coals weighing 84 lbs.; this makes the consumption of such an engine very near two bushels *per* hour; an eight-horse burns one bushel. We have also taken the performance of the engine of 100 horses at 30 millions, and made all the intermediate sizes by a regular law of increase; the result agrees so well with several engines which we have observed, that we considered the Table as very correct. The quantities of coal are the smallest; scarcely any engines will do with less fuel when they are working with their full load; but many engines will require more. Engines will be constantly found which are of the dimensions marked in our Table, and are called so many horse-power, although they are working with either a greater or lesser power than the Table expresses; in such cases, allowance of fuel must be altered in proportion.

We have now gone through the description of those machines for raising water which are actuated by the mechanical force of animals, or water or steam acting externally by means of levers and other connecting mechanism; but there are some machines in which a current or a column of water is made to operate within close vessels, and raise water to a considerable height: these are the Chremnitz fountain, the sypho interruptus, and the hydraulic ram. These are most admirable machines, particularly the last, because they are so simple, and having scarcely any moving parts, are not liable to decay and injury; and they do not waste the motive power in unnecessary friction and resistance.

The original steam-engines of the marquis of Worcester and Savery, which are all of this class, are fully described under the article *STEAM-Engine*. The waste of fuel in these engines is so great, that they fall very far below other engines. We have mentioned the engine made by Mr. Kier, which by a calculation will be found to raise only $2\frac{3}{4}$ millions of pounds of water one foot high with each bushel of coals, and the power of the engine is $2\frac{3}{4}$ horses. An engine of the same kind, of five horses power, which Mr. Smeaton calculated raised $5\frac{1}{2}$ millions, and this is perhaps the utmost of this kind of engines. Another engine of $2\frac{3}{4}$ horse-power, raised $5\frac{1}{2}$ millions. The best engine on Newcomen's principle will raise 10 millions; Mr. Watt's 30 millions; and Mr. Woolf's 50 millions. From this statement, it is clear that the expence of fuel in Savery's engines is so great as to counterbalance any advantages arising from their simplicity.

The Chremnitz Machine.—In this a column of water, descending from an elevated reservoir, is made to raise up another column of water from a considerable depth, and air is introduced as the medium for communicating the pressure of the motive column to that column which is to be raised. This machine is not a new invention; its principle is fully described in the Italian book, "Le Machine," by Brancas of Rome, 1629. A machine at Chremnitz, in Hungary, is so celebrated as to have given a name to this invention from its size, and the most extraordinary formation of ice and snow by the working of it, besides that it is the only one of the kind which had been applied to large works. An account was given to the Royal Academy at Paris by their correspondent M. Jars, which is inserted in their memoirs for the year 1768; and Dr. Wolfe has also described it. The machine was executed by father Hell, a professor of astronomy at Vienna, in the year 1755; it is used to raise the water in a shaft named Amalie, in the mines at Schremnitz, or Chremnitz, in Hungary; *fig. 14. Plate Water-*

ter-works, is a sketch of this machine, in which the pipes are not drawn in the proportion of their lengths, but are contracted to the space of the design. O is a wooden trough, placed in the middle of the mountain, 143 feet above the place, K, where the water drains off; this water is conveyed from the mines above it, and the fall of the water from this reservoir works the machine. There is also another trough higher up the mountain, *viz.* 260 feet above the place of delivery K, into which rain-water is conveyed for the purpose of working the machine with 260 feet fall, when a supply can be obtained therefrom; but when this supply fails, the machine is worked by the cistern O with 143 feet fall. T is an iron-pipe descending from the reservoir, to convey the water to an air-vessel of copper, A, placed at the foot of the mountain near the place of delivery. The water from the reservoir O, or from the more elevated reservoir, flows through the descending pipe T, whenever the cock H is opened: the pipe T descends very nearly to the bottom of the vessel A A, as shewn by the dotted lines X, with the intention that the air included in the vessel shall be compressed when the water enters, and forced through the tube L M into a lower vessel, B, which is similar to A, but only of half the capacity; it is placed at the bottom of the lower mine, which is to be drained at 104 feet below the delivery K, and vessel A; this lower vessel receives the waters collected in this mine from the trough D, through the pipe Q and cock C, and by the force of the compressed air introduced into B by the pipe M from the upper vessel; the water contained in B is expelled through the pipe S, which descends to the bottom of the vessel B, and is discharged at F.

The wooden trough D is the termination of a trough or channel from another engine, which raises the water from a yet greater depth; K is a pipe with a cock for discharging the water out of the vessel A, when the operation is over, in order to fill it again with air ready to repeat it, for which purpose the small pipe I is likewise opened to admit air; the cock L transmits and discharges air from the upper vessel A into the lower vessel, through the pipe M. The little pipe E, and its turncock, must be opened to let out the air from the vessel B, and it must remain open whilst B is filling, by the water from the trough D, through the pipe C Q, and it is at the orifice of the little pipe E that snow and ice are generated. A valve is placed at the lower ends of the pipe F S, to prevent the water from escaping out of the pipe F S, after it has been raised, and whilst the vessel B is filling with fresh water.

The operation is performed thus: two men are placed at the vessels A and B to open and shut the cocks; suppose all the cocks shut, and the reservoir O, at 143 feet high, is always full; the pipe T H is also full as far as the cock H; the reservoir D is kept constantly full of water from the mine, which is to be drained by raising the water from D to F, 104 feet; for this purpose, it must first be admitted into the vessel B: the cock C is therefore opened, and the water flows into B, the air being at the same time suffered to escape from that vessel by opening the cock E. The vessel B is known to be full by the emission of water at E, at which instant both the cocks C and E are to be closed. The machine is now prepared for the operation, which is began by opening the cocks H and L; the descending water from the reservoir O enters the vessel A, and compresses the included air till its elastic force becomes equal to the pressure of the column of water D F, and then the air descends through the pipe M, and enters the lower vessel B, where it presses on the surface of the water contained in the vessel, and forces that water to ascend through S to F, which opens into the adit, through

which the water is discharged from the mine. This water being raised, the lower vessel B is become filled with condensed air in place of the water, and the upper vessel A is become filled with water in place of the air. The cocks H and L are then shut, and K and I are opened; the cock K suffers the water contained in A to flow off, and I accelerates the discharge, by admitting the external air into the vessel A; and both these cocks are closed again as soon as the evacuation of the upper vessel is completed. During this last operation another man below opens the cock E, by which the condensed air included in the vessel B issues with great force through E; he then opens C, and the water from D again fills the vessel B, as at first; this being done, he closes C and E.

The apparatus is now charged again ready for action, and by opening H and L the above operation will be repeated; *viz.* the contents of B will be forced up to F, and thus the engine may be kept continually at work as long as the two reservoirs O at the top, and D at the bottom, are kept supplied.

The dimensions of the principal parts, as given by father Hell, are as follow, in Hungarian measure:

The diameter of the upper vessel A $32\frac{1}{2}$ inches; its height 60 inches; the thickness of the copper $1\frac{1}{4}$ inches.

The iron-pipe T is 260 feet; from H, to the most elevated reservoir above O, it is $4\frac{1}{2}$ inches bore; and the thickness of the metal is $1\frac{1}{4}$ inches.

The lower reservoir O 143 feet above H.

The pipe F S, 104 feet long, $3\frac{1}{2}$ inches bore.

The air-pipe L M is formed narrower towards the bottom; at its upper end it is two inches bore, and at its lower end 1 inch; thickness of the metal $1\frac{1}{4}$ inches.

The Chremnitz foot is to the Paris foot, as 1538 to 1440; the pound, as 106 to 92. The Paris foot to the English, as 32 to 30.

A cubic foot of water of the mine weighs 72 lbs.

The upper vessel A contains $57\frac{1}{2}$ cubic feet, and the lower vessel B $27\frac{1}{2}$.

Twenty-five cubic feet are raised at every operation, and sometimes $31\frac{1}{2}$ feet, as the water descends from the upper or lower reservoirs at O, the duration of the operation being different; for when the upper cistern O is used at 260 feet of elevation, 20 or 21 draughts are made in an hour; but when the lower cistern is used at 143 feet elevation, only 17 or 18 draughts *per* hour.

Each of these vessels is cast in three pieces, which are joined by flanches and screws, with a ring of lead and another of leather placed between each to secure the joint, and prevent the transmission of any fluid. M. Jars observes that the pipes would have been better if connected by flanches, in the manner shewn by the figure; but the real practice is to drive the ends of the pipes into hollow cylinders of dry wood, bound with iron hoops; these answer tolerably well, and are of considerable durability.

The moveable plugs of the cocks, C, E, K, are screwed in their places by caps or covers fastened down with screws.

The produce of water raised by this machine is thus estimated by Dr. Wolfe:

If the vessel A were completely emptied after each operation, the expence of water, when the fall of 260 feet is used, would be 1178.25 cubic feet in an hour, descending 206 feet; and the effect, or the water raised, would be 563.75 cubic feet to a height of 104 feet; or, when the fall of 143 feet is used, the expence *per* hour would be 1006.25 cubic feet, and the effect 481.25. But as it is not necessary that the vessel A should be much more than half emptied, the expence of water will be nearly equal to, or will not much exceed the quantity raised.

It should follow, from experiments on the nature of air, that the column FD is counterpoised by the compressed air in the inverse ratio of 104 to 32: hence the volume of air contained in the vessel A and the pipe LM, equal to $58\frac{1}{2}$ cubic feet, must be reduced to 18 cubic feet, before the elasticity will be equal to the pressure of the column CF 104 feet; but by increasing the compression a little more, the water in B will be made to flow out through F.

If, at the moment the vessel A is full of water, the cock H be shut, the water will continue to flow through F, until the air occupies a space of 18 cubic feet in the vessel B, and in the pipe LM; the elasticity of the air will then be in equilibrio with the column FD, and the efflux of the water through F will cease. In this manner, not above 17 cubic feet of water are evacuated at each draught, and $10\frac{1}{2}$ cubic feet are constantly left in the vessel B.

But if the cock H is not shut the very moment that the vessel A is full, the water in A will follow the air through LM, and, before it gets to the vessel B, will raise one cubic foot more out of that vessel. After the water from A enters into the vessel B, the discharge at F will not be the water of B, but the water of A descending and ascending again by a useless circuit, until H be shut; which being done, the water will continue to flow at F, until the remainder of $10\frac{1}{2}$ cubic feet is expelled from B by the air contained in it. The moment when the water from A has descended into the lower vessel B may easily be known, by the velocity of the efflux at F becoming suddenly three times greater.

That this is actually the case is proved, because sometimes $31\frac{1}{2}$ cubic feet are discharged; which quantity exceeds the capacity of the vessel B by more than 4 cubic feet.

This inconvenience might easily have been prevented, by giving to the pipe S a diameter of 18 inches; for then there would have remained only the just space of 18 cubic feet for the compressed air.

The height of the column T to the lowest of the two reservoirs at O is 143 feet, which, taken upon the diameter of the vessel A as a base, is equal to the weight of $822\frac{1}{4}$ cubic feet, and would compress the air into a fourth; or, when the water is descending into the lower vessel B, into a seventh part of its natural space, provided it were equally resisted at F. The vessel A becomes filled at a mean in 8 seconds; and in twice that space of time, 17 cubic feet are evacuated through F.

The power of the column of 260 feet from the most elevated reservoir, acting within the vessel A, is equivalent to the weight of 1495 cubic feet of water. It can raise a greater quantity, if the vessel B be so constructed as to allow no more than a just space to the compressed air. If the vessel A were filled in 4 seconds, then 17 cubic feet of water would be discharged through F in twice that time, and the air would be reduced into an eighth, and, during the descent of the water of the vessel A into the lower vessel B, into an eleventh part of its bulk. But this makes no alteration as to the quantity of the effect; and when water ceases to flow out at F, there will always remain $10\frac{1}{2}$ cubic feet of water in the vessel B.

Two men are required to attend it, but it would be very easy to connect the levers of the cocks above and below, so as to require only one man to work the whole set; and indeed there would be little difficulty in making the machine work itself safely, without any attendant, except to set it off at first, or stop it when requisite. The machinery for this purpose has been proposed by Mr. Boswell. See Nicholson's Journal, 4to. iv. 117.

From what has been said, it is evident that this machine,

though it answers the author's intention, is so deficient as to the effect the same fall of water might produce, as to bear scarce any proportion; and there is a defect in the principle of the machine, *viz.* that the air will require a considerable share of the power to compress it, and this air must be suffered to escape, before the vessels can be refilled to repeat the action; in consequence, all the power taken to compress the air is lost, and expands itself in forcing out a strong blast of air at the discharging cock, without producing any useful effect. Notwithstanding this defect, the cheapness and ease of construction, and the little wear and tear, together with the facility with which it may be made to work and stop for very short periods of time, are powerful recommendations of this machine, in such places as afford the requisite fall of superior water, and do not require a higher single lift than 15 or 20 fathoms.

A curious phenomenon has been observed in this machine, when it is near the end of its operation, that is, when nearly the whole of the water has been raised out of the lower vessel B, and the cock E be opened to give vent to the compressed air, and before the cock L is shut, so that the air is followed up by the water, then if a hat or miner's bonnet be presented to the aperture E, the aqueous vapours dispersed through the compressed air, and perhaps also, says M. Jars, part of those of the external air are condensed in the bonnet in the form of very white and compact ice, very much resembling hail, and not easily separated from the bonnet. It soon melts, which is not to be wondered at, as the temperature of the place itself is not cold. Messrs. Du Hamel and Jars remained in Hungary from January to July 1758, and observed the same phenomenon at all seasons; but as they had no thermometer, they could not make a number of experiments, which might have been of value in the investigation of the subject.

It is observed that the air issues out with such impetuosity, that the workman could not hold the bonnet at the distance of a few inches from the aperture, as he does in this experiment, if he were not supported behind. The ice is much more compact, if the cock be only in part opened.

When the cock at which the air is discharged is opened, it rushes out with prodigious violence, and the drops of water are changed into hail or lumps of ice. It is a sight usually shewn to strangers, who are desired to hold their hats, to receive the blasts of air: the ice comes out with such violence as frequently to pierce the hat like a pistol bullet. This rapid congelation is a remarkable instance of the general fact, that air, by suddenly expanding, generates cold; its capacity for heat being increased.

The formation of the ice and snow, when the condensed air rushes out of this machine, has been explained in a different way in almost every system of philosophy. It appears to us to be a necessary consequence of the condensed air, on rushing out into the open air.

The air of the atmosphere, and the water when taken into the machine, are nearly of the same temperature; and it may be considered that each cubic foot of water and of air contains some certain quantity of heat or caloric; but they will readily impart a portion of this heat to any body containing a less degree than themselves, or they will absorb or take up heat from any body containing a greater proportion of heat than themselves, in consequence of that property of heat, by which it will distribute itself equally among all bodies which are in contact with each other. By the action of the machine, the air is compressed into one-third of the space it before occupied, and the share of heat contained in that air is likewise concentrated or thrown into a third of the space, and in consequence becomes more intense. Some part of

the heat will, therefore, be communicated to the surrounding water, until the heat distributes itself again between the water and the condensed air, so that they come to the same temperature. In this state, if the air is suffered to rush out of the vessel, it will suddenly expand and recover its former volume, and it must also recover its former share of caloric, which it can only do by abstracting heat from the surrounding air, or from any substance with which it comes in contact: hence the coldness of the blast of air. In respect to the formation of snow and ice, it must be considered that the air of damp places always contains a considerable portion of water in a state of vapour, and the air in this machine will have taken up more than the ordinary share, in consequence of being in contact with the water. When the air expands itself, the heat being suddenly abstracted from this watery vapour, it becomes fluid, and accumulates in drops like rain; which drops, by a farther abstraction of heat, become solid like snow or hail.

An instrument which is in common use to produce fire, by the sudden compression of air, shews the reverse of this action: it is a syringe fitted with a piston, which is air-tight; at the bottom of the barrel a small piece of tinder is placed. Now, if the piston is very violently and suddenly forced down to the bottom of the barrel, and the piston is then withdrawn, the tinder will be found on fire. The heat contained in the air which fills the barrel is so concentrated at the same time with the air, as to produce actual fire. If the piston is forced slowly down, the air will be condensed to an equal degree, but no fire will be produced, because the heat has time to escape through the metal of the barrel, before it arrives at any considerable degree of concentration. We consider that in all cases when air (and perhaps other elastic fluids) is compressed into a smaller space, part of the heat it before contained will be given out to the surrounding matter; or if it is suffered to expand to fill a larger space, it will absorb or take up heat from the surrounding matter.

A larger Machine at Chremnitz.—This does not differ from the original machine, so as to require a minute description; but as this machine is not employed in England, and we think it might be useful in many cases in mining districts, we shall give the proportions and calculations of a larger machine, as a model for engineers.

	Feet.
Height of the source above the place of delivery or fall of water, which is to work the machine: descending pipe 4 inches bore	136
Depth from which the water is to be raised out of the pit to the place of delivery: ascending pipe 4 inches bore	96
	Cubic Feet.
Upper vessel a copper cylinder 5 feet diameter, and 8½ feet high; metal 2 inches thick; the descending pipe goes to within 4 inches of the bottom: contents	170
The lower vessel a brass cylinder 4 feet diameter, and 6½ feet high; metal 2 inches thick; the ascending-pipe goes within 3 inches of the bottom: capacity	83
Air-pipe which communicates between the two vessels, 2 inches bore, and 96 feet in length	}

To understand the action of this machine clearly:—Suppose that the lower cylinder is charged with water, and the upper cylinder with air ready for action; when the water from the source is admitted into the upper cylinder, if no issue was given to the contained air, the water would enter into the vessel, until the air was compressed into one-fifth of

its bulk by the column of 136 feet high; for a column of 34 feet nearly balances the ordinary elasticity of the air. But when there is an issue given to the air through the air-pipe, it will drive the compressed air along this pipe, and it will expel water from the lower cylinder.

When all the air is expelled from the upper cylinder, there will be 34 cubic feet of water expelled from the lower cylinder. Now if the ascending pipe had been carried up more than 136 feet above the lower level, instead of 96 feet, then the water would have risen 136 feet high in that pipe, by the intervention of the elastic air, before it was in equilibrio with the water in the descending pipe; but no more water would have been expelled from the lower cylinder than what would fill this pipe.

But the ascending pipe being only 96 feet high, the water will be thrown out at the top of it with a considerable velocity. Were it not for the great obstructions which the water and air must meet with in their passage along the pipes, it would issue from the mouth of the ascending pipe with a velocity of more than 50 feet per second. It issues, however, much more slowly.

When the upper cylinder is become filled with water, the supply is stopped; but the lower cylinder still contains 34 cubic feet of compressed air of sufficient elasticity to balance the water in a discharging-pipe 136 feet high, whereas the ascending-pipe is only 96 feet. Therefore the water will continue to flow at the mouth of the ascending-pipe till the compressed air is so far expanded as to balance only 96 feet of water, that is, until it occupies one-fourth of its ordinary bulk, or one-fourth of the capacity of the upper cylinder, viz. 42½ cubic feet. Therefore 42½ cubic feet of water will be expelled, and then the efflux will cease, leaving the lower cylinder about one-half full of water.

When the discharging-cock of the upper vessel is opened the water issues with great violence, being pressed by the condensed air returning from the lower cylinder. It therefore issues with the sum of its own weight, and of this compression. These gradually decrease together, by the efflux of the water and the expansion of the air; and this efflux stops before all the water in the upper vessel has flowed out, because there are only 42½ feet of the lower cylinder occupied by air. This quantity of water nearly will therefore remain in the upper cylinder. The workman knows this, because the discharged water from the upper vessel is received first of all into a vessel containing three-fourths of the capacity of the upper cylinder, which serves as a measure; when this is filled, the attendant opens the cock which admits the water into the lower vessel, by a long rod which goes down the shaft: this allows the water of the mine to fill the lower cylinder, and the air returns into the upper cylinder through the air-pipe, and permits the remaining water to run out of it; and when the attendant finds no more water will come out, every thing is brought to its first condition.

The above account of the procedure in working this engine, shews that the efflux at the mouth of the ascending-pipe becomes very slow near the end. On this account, it is found convenient not to wait for the complete discharge, but to cut off the supply when about 30 cubic feet of water have been discharged, and more work is done in this way.

A gentleman of great accuracy and knowledge of these subjects, took the trouble of noticing particularly the performance of the machine. He observed that each stroke, as it may be called, took up about three minutes and one-eighth, and that 32 cubic feet of water were discharged, and 66 cubic feet were expended.

The expence therefore is 66 cubic feet of water falling

WATER.

136 feet, and the performance is 32 cubic feet raised 96 feet, and they are in the proportion of 66×136 to 32×96 , *viz.* 8976 to 3072, that is the power employed is to the effect produced, as 2.9 to 1. The quantity raised, *viz.* 32 cubic feet, divided by the time $3\frac{1}{2}$ minutes, gives very nearly 10 cubic feet *per* minute, and multiplied by the height raised 96 feet = 960 cubic feet raised 1 foot high. Divide this by 528 cubic feet, which is the horse-power, and it gives 1.8. The machine is not therefore equal in effective power to a steam-engine of two-horse power, but the power employed is just equal to five-horse power.

When we consider the great obstruction which water meets with in its passage through long pipes, we find we may gain some advantage by increasing the bore of the descending-pipe of supply. The quantity of water which descends through this is 66 cubic feet in $3\frac{1}{2}$ minutes, or very nearly 30 cubic feet *per* minute; the area of the four-inch bore is 12.5 square inches, and therefore 11.5 such areas would make a square foot. Multiply 30 cubic feet by 11.5, and we have 345 feet, which is the velocity with which the water must descend in the pipe. This is much too great, and it would be an improvement if the pipe was increased to six inches bore, and the velocity would then be only 151 feet *per* minute. The performance of the machine would then be greatly increased, we think as much as one-third; it is true that it would expend more water, but not in the same proportion; for part of the deficiency of this machine arises from the needless velocity of the water in the pipe, as well as from the violent efflux of the water by the condensed air, as we have before mentioned.

The discharging-pipe ought to be 110 feet high instead of 96, and would not give sensibly less water. It must be considered if the original expence of this simple machine would not be less than a water-mill which would raise 10 cubic feet of water, 96 feet high, in a minute; the repairs of it would be small when compared with a mill. And, lastly, let it be noticed, that such a machine can be used where no mill whatever can be put in motion.

A small stream of water, which would not move any kind of wheel, will raise one-third of its own quantity to the same height, working as fast as it is supplied.

From its simplicity, we think the HUNGARIAN Machine (which see) eminently deserves the attention of mathematicians and engineers, to bring it to its utmost perfection, and into general use. There are many situations where this kind of machine may be very useful. Thus where the tide rises 17 feet, it may be used for compressing air into seven-eighths of its bulk, and a pipe leading from a very large vessel inverted in the tide-water may be used for raising water from another vessel of one-eighth of its capacity, 15 feet high; or if this vessel has only one-tenth of the capacity of the larger one set in the tide-way, two pipes may be led from it, one into the small vessel, and the other into an equal vessel, 16 feet higher, which receives the water from the first. Thus one-sixteenth of the water may be raised 34 feet, and a smaller quantity to a still greater height, and this with a kind of power that can hardly be applied any other way.

Sipho Interruptus to raise Water by Suction.—This machine is the reverse of the Chrennitz machine in its action, for the power of a descending column of water, running out of a close vessel, causes a vacuum therein; and another column of water is sucked up into the vessel, or rather forced up by the pressure of the atmosphere to fill the vacuous space. This machine is fully described by Leopold, in his *Theatrum Machinarum Hydraulicarum*, vol. i. It is provided with apparatus to open and shut the cocks. It would be difficult to explain this machine without several figures, and we

have therefore preferred to describe a machine of the same kind invented by Mr. Goodwin; he calls it a machine that will raise a body of water to any height not exceeding the height of that column which will counterbalance the pressure of the atmosphere, (say 30 feet) and acts by the descent of part of the same body of water through a somewhat greater height, aided by the pressure of the atmosphere.

Let A, *fig. 10, Plate Water-works*, be a spherical vessel of copper or other metal, about 18 inches diameter; B, another sphere, about two feet six inches in diameter; C, a reservoir kept constantly supplied with water, part of which is to be raised up to E, by the power of another part descending to a considerable depth beneath the reservoir C. D is a glass cap, about six inches long, fixed on the top of the upper vessel A, for the purpose of seeing when the water begins to fill and has filled it; E is the upper reservoir into which the water of the reservoir C is to be elevated, and the contents of the upper vessel A is to be emptied; 1 is a pipe about half an inch in diameter, joined into the top of the lower vessel B, and rising upwards to within about an inch of the top of the glass cap D of the upper vessel; 2 is a pipe of the same diameter, and a few feet longer than 1, 1, joined to the bottom of the lower vessel B, and descending downwards in a perpendicular or inclined direction, to a rather greater distance beneath C than the upper vessel A is elevated above C; 3 is a pipe one inch and a half in diameter, joined to the bottom of the upper vessel A, and passing upwards through the bottom to within two inches of the top of the glass cap D; 4, 4, is a pipe of about half an inch diameter, joined to the top of the vessel B, it passes through the bottom of the reservoir C, and rises above the surface of the water therein; 5 is a pipe of the same diameter, fixed to the top of the vessel B, and terminating in and fixed to the bottom of the reservoir C; a is a pipe or spout of the same diameter, fixed into the bottom of the upper vessel A, to convey the water into the reservoir E; 7 is a trumpet mouth-pipe fixed to the bottom of the pipe 3, and extending downwards beneath the water to within about an inch of the bottom of the reservoir C; a, b, c, and d, are cocks fixed to the pipes. The vessels, pipes, cocks, and joints, must all be air-tight.

In order to raise water from the lower reservoir C into the upper reservoir E, all the cocks being shut proceed thus: open the cocks b and c, in order to fill the lower vessel B, and when B is filled, shut the cocks b and c, and open the cock d. The water will then begin to run from the sphere B by its gravity, and by means of its communication with the upper sphere A, through the pipe 1, will draw off the air therefrom to supply the space left in the lower vessel B, by the running out of the water the air in A is thus rarefied. The atmospheric air at the same time pressing on the water in the reservoir C, will cause it to rise through the trumpet-mouth 7 of the pipe 3, and by falling over the top of the pipe 3 at D, it will fill the upper sphere A. When A is full, which may be seen through the glass cap D, shut the cock d, and open the three cocks a, b, and c, the cock and pipe b will allow the atmospheric air to return into the vessel, and fill both with air, by which means the water contained in the vessel A will run into the elevated reservoir E, and B will be replenished for another operation. Then shut the cocks a, b, and c, and open the cock d, and it will repeat the operation of raising the water into A.

If it be required to raise any body of water from reservoir C into reservoir E, by means of the descent of a body of some other water from the vessel B, a communication must be made into B, independently of the pipe 5, and

cock *c*; viz. through a pipe-cock leading from another reservoir, as is represented by the dotted lines communicating with B near the pipe and cock 5; the action is the same as before; but the cock with the dotted lines is to be used in lieu of pipe 5, and cock *c*. By this means, if the water which is employed to work the machine is foul or tainted, it will have no communication with the water which it raises. This machine has the same defect as the Chremnitz machine; viz. that the power which is expended in rarefying the air is greater than the quantity of water raised, and the difference is lost when the cock in the lower vessel is opened, and the air rushes in.

A different Form of the Siphon Machine.—Mr. Goodwin's engine is formed upon a very elegant principle, and operates by the assistance of only a small quantity of water. It may be made in various forms, either to raise the fluid above the descending column, or from below it to a level with the bottom, and the height may be doubled or trebled by proportionally increasing the descending mass, and raising several columns of water from different elevations at the same time, by combining two or more of the simple machines together, as is shewn in *fig. 8. Plate Water-works.*

C, as in the former figure, represents the reservoir or source of water which is to work the machine; B represents the lowest of the two vessels which contain the rising and descending bodies of water; and the small square near *fig. 8.* represents the upper vessel A, *fig. 10.* These vessels are spherical in the original drawing, but to lessen the loss of space in descent, they are here made flat and cylindrical; E is the higher cistern of the original figure, into which the water is to be raised; 2, 3, and 4, are the pipes arranged in the same manner as the former machine; F, a vessel the same as A, with tubes 3 and 6: it communicates with the vessel B by a pipe, and is intended to raise water out of the cistern E into a higher and additional cistern G.

The vessels E, F, and G, form a second machine, which has the same parts and properties as the former, except that the lower vessel B is common to both, and serves as the lower vessel to exhaust and drive up the water both to A and to F; 2 is an enlarged tube like the original drawing, through which the water descends to produce the action; 5 is a hole in the top of B, instead of a tube. This hole, and the tubes 2, 4, and 6, must be provided with valves instead of cocks, which must be kept close by weights or springs, (while the water is rising) except the valve to tube 2, which must be open. The tubes 3, 3, may also have valves to support the raised columns.

Operation.—Fill the cisterns C and E with water, and let the lower cistern be constantly supplied; open the valves of the tubes 4, 5, 6, 6, and close the valve of the descending-tube 2, the vessel B then becomes filled through the hole 5. Now close the valves of the tubes 4, 5, and 6, and open the valve of the tube 2, the water will then begin to descend out of B, and will exhaust the air from A and F, just as in the first-mentioned machine; the pressure of the atmosphere on the surface of the water C, will raise one body of water out of C into A, and out of E into F; when B is nearly empty, or when A and F are full, open the tubes 4, 5, 6, 6, and close 2, then B will be filled a second time, and the vessels A and F will empty themselves into their respective cisterns E and G: thus the reciprocations continue without interruption.

Another body of water may be raised out of G into a higher cistern by additional apparatus, and by proportionally increasing the dimensions of the vessel B and the tube 2. The dotted lines represent the apparatus for raising water

below the bottom of the tube 2, to be used instead of those above the cistern C.

This arrangement of the engine is of great utility in many cases; and in situations where this machine can be erected, it may be of considerable use for raising water out of mines for draining pieces of land, or elevating the water employed in domestic purposes.

Comparison of different Pressure-Engines.—In Mr. Nicholson's Journal, 8vo. vol. i. Mr. Boswell has given a plan for constructing Mr. Goodwin's engine on a large scale, to operate without attendance of any person, to open and shut the cocks, and another method of causing the Chremnitz machine to raise water above the level of the prime reservoir; and he makes the following comparative view of the advantages of both kinds of engines and their powers.

It will be found that the powers and capabilities of these machines are nearly similar. 1st, In both the greater the height of the original fall of water from the source to the discharge, and the greater the quantity of water which it can supply in a given time, the greater quantity can be raised by either of these engines in a given time. 2dly, Both engines can be constructed so as to raise water above the original level, and from below, to the surface, or from a pit. 3dly, By a successive number of reservoirs, both engines can be brought to raise water to any height, but as they will raise a smaller quantity as the height is increased, the quantity wanted in a given time, and the expence of construction, will limit the extent of their elevation. 4thly, In both engines the distance of one reservoir from another must always be less than that of the original fall: the circumstances in which these engines differ arise from the difference in their manner of action. 5thly, The Chremnitz engine operates by causing a fall of water to compress the air, which reacting on other water, forces it to rise in a pipe to a certain height. The syphon engine acts by causing a fall of water to rarefy a certain quantity of air, in whose space the pressure of the atmosphere forces a quantity of water when permitted. 6thly, Hence in the Chremnitz engine the pressure acting from within outwards tends to burst the vessels used in the structure, and to open and extend any fissures which may chance to be in them. 7thly, In the syphon engine, the pressure acting from without inwards, closes all the parts of which it is composed more together. 8thly, The Chremnitz engine will always raise water of a height nearly equal to that of the original fall from one reservoir to another, supposing the original fall of any height whatsoever as 100 feet. The syphon engine will not raise water by one reservoir so high as thirty feet in any case whatsoever, as there cannot be a complete vacuum formed by it in the air-chamber, but only an approximation to one.

From this comparison, it will follow that wherever the original fall of water is less than thirty-two feet, the syphon engine will be much preferable to the Chremnitz, as from the seventh article of the comparison it may be made of the cheapest materials, such as strong wooden casks and wooden pipes, whereas the Chremnitz engine from the sixth article must be made of the strongest, and of course the most costly materials, as metal, and that of considerable thickness; but wherever the original fall exceeds the height of thirty feet considerably, and it is required to raise the water to nearly the same height, then the Chremnitz engine appears to be preferable, as, in all probability, the fewer number of parts which it will require in this case will more than compensate for its cost in materials.

When it is required to raise water to a height much greater than that of the original fall above the first level, or from a greater depth, either from the original fall being short, or the

the required height being great, it is better to employ an engine in which the pressure of the water is made to act by a piston in an apparatus similar to that of a steam-engine. (See our article *PRESSURE Engine*.) When neither the syphon engine nor the Chrennitz can be used without a number of reservoirs, then the piston pressure-engine ought to be preferred, but this will much depend on the number of reservoirs; for perhaps one or two in addition to the Chrennitz might cost less than boring the cylinder of the piston-engine perfect, and constructing its additional machinery. For merely raising water the powers of each are nearly equal, depending entirely on the height of the original fall of water.

It would be a great advantage of the piston-pressure engine if a fall of water could be applied to it without any waste, to work mills or machinery for any purpose; this would be of very great consequence when the fall of water is of considerable height, and the stream or supply small. We have mentioned the advantage in this engine to have its action made elastic, by the addition of an air-chamber, on the same principle as that used in engines for extinguishing conflagrations. Mr. Boswell suggests that this might be effected by making the piston hollow, and of a larger size, to contain air for this purpose, as the air's elasticity would then act both on the upper and lower pressure of the water.

Machine for raising Water by the lateral Communication, from the Motion of a Stream of Water running through a conical Tube.

—This machine operates by suction, or more properly by the pressure of the atmosphere, and is in some respects similar to the syphon machine. (See *fig. 9. Plate Water-works*.) A A represents a reservoir of water kept constantly full, at the same time that the conical spout, B, is running full under a considerable pressure; D, a spherical copper vessel, with a tube, C, joined into its bottom, and rising up within to some height above the centre of the sphere; E, another tube joined to the bottom of the sphere D, and terminating near its top; the lower part of this tube is bent, and the extremity of it is introduced into the smaller apertures of the conical tube B; F, a spout or tube to empty the vessel D, when it is filled with water which has been raised up out of the reservoir A; G, a small tube passing through the spout F, and rising to near the top of the sphere, D, for the admission of air to quicken the descent of water out of that vessel. Both these tubes are closed at their lower ends by a leather valve at the end of the lever L, which lever is fixed upon the turning plug of a cock in the tube E, and has a weight upon one end, in order that the other end may bear the valve up against the openings of the tubes F, G, with a considerable force, and also to support the weight of the small bucket I, which is suspended from the lever by a wire (at least when the bucket is empty); H is a small cistern to be filled with water from the reservoir A, in the same time that the water is raised up into D; this must be done by regulating the cock, k, upon the pipe which supplies the cistern with water. The cistern H is provided with a syphon, which will begin running as soon as the vessel is full of water, and will soon empty it. The small bucket I, which is suspended from the lever L, is also furnished with a syphon-tube, which will begin to run and empty the bucket whenever it is quite full, but not before.

The operation of the engine will be as follows:—The reservoir A being kept constantly full of water, and the conical tube B completely filled at its wider end by the water which runs out of A, the force of the lateral motion of the fluid will be increased by the conical form of the tube B, and will act upon the end of the tube E to draw air out of the same, so as to rarefy the air in the vessel D; and the pres-

sure of the atmosphere upon the surface of the water in the reservoir A, will cause part of that water to rise up the pipe C, to run over its top and fill the sphere D; it will then descend through E, and join the stream of water which flows out at B. When the vessel D is full of water, if the valve at the spout F is opened, the water will run out.

In order to open the valve the cock k is regulated, that the cistern H will be filled soon after D is full, and the syphon of this cistern beginning to empty the water it fills the bucket I, which then overbalances the weight upon the lever L, and opens the spout F, and air-pipe G, and at the same time closes the cock in E; the column of water in the descending pipe C immediately descends into the reservoir, and if the small tube G be full of water it will be emptied by the descent of that column, and will admit air into D so as to allow the water to flow out at F into the elevated reservoir. The syphon in the cistern H is regulated so that the cistern and the vessel D will be empty of water about the same time, and the bucket I by its syphon will become empty soon after: the weight upon the lever L will then close the spout F, and open the passage through E, when all the parts will stand as at first ready for a repetition of the operation of the lateral action of the stream, by which the water is raised up into D as before.

If the water should descend through E before F and G are opened, it will render the cock in E more tight. To quicken the reciprocation of the engine, and increase the quantity of raised water, a valve may be made to support the column of water in the suction-pipe; this valve may be placed in a chest at the bottom of the pipe.

The descending branch of the syphon in the higher vessel H should be made of considerable length, to prevent a constant dripping, and make the reciprocation end at once; the syphon of the bucket I should fall as large in bore as the other, in order that the weight on L may preponderate quickly, and close the valve immediately.

The inventor entertains no doubt respecting the operation of a machine of this kind, and that a column of water may be raised to any height not exceeding thirty feet by proportionally increasing the pressure of water in the reservoir, and the dimensions of the conical tube.

In many situations, however, the requisite quantity of water for this purpose cannot be had, and others may not admit of sufficient descent.

Where the stream has a considerable descent, the water may be raised by a number of lifts instead of one, by combining as many machines. Suppose three reservoirs each with its conical tube or spout through which the water runs from one to the other; also three exhausting vessels each with its elevated cistern into which the raised water is to be delivered; and the suction-pipe of each vessel draws its water from the elevated cistern of the vessel below it. From each exhausting vessel a pipe is conveyed to the conical spout of one of the three reservoirs, and the lateral motion of the stream passing through the spouts of the three reservoirs will act upon all three engines at once.

In like manner, when there is plenty of water, but not convenience for a deep reservoir, several conical spouts may be fixed to different parts of the reservoir, and all upon the same level. Each machine must be provided with a lever and weight to work its own valves, but they may be all opened at the same time by the descent of one vessel connected with all the levers, or each may have its respective bucket and syphons.

This kind of machinery, by altering the position of the rarefying tubes, may be made to raise water from a depth below the stream equally as well as to a height above it; and

in situations where there is plenty of water and convenience for a reservoir a lower body of water may be conveyed into a stream above by the help of a single tube, one end of which is placed in the water to be raised, and the other must be introduced into the smaller aperture of the conical tube adapted to the reservoir; a constant stream will then rise, so long as water below can supply the tube.

Mr. Whitehurst's Machine for raising Water by its Momentum.—Fig. 7, *Plate Water-works*, is a representation of the first machine on this principle, which was executed in the year 1772, by the ingenious Mr. John Whitehurst, at Oulton in Cheshire, at the seat of Mr. Egerton, for the service of a brew-house and other offices, and which purpose it was found to answer effectually. This first form of the momentum machine would be a useful application in many similar situations. The circumstances attending this water-work are as follow: A represents the spring, or original reservoir, which supplies the water, the upper surface coincides with the horizontal line BC, and the bottom of the reservoir K, into which the water is to be raised; D is the main-pipe, one inch and a half in diameter, and nearly two hundred yards in length; E, a branch-pipe, of the same dimensions, for the service of the kitchen-offices. It is to be observed, that the kitchen-offices are situated at least eighteen or twenty feet below the surface of the reservoir A; and that the cock F is about sixteen feet below it. G represents a valve-box, and *g* the valve within it; H is an air-vessel, and O, O, are the two ends of the main-pipe, inserted into the air-vessel H, and bending downwards, so that in effect the pipes communicate with the lowest part of the vessel, and the air cannot escape when the water is forced into it, but it must be compressed by the column of water; W is the surface of the water in the air-vessel. It is well known from theory that, when water is discharged from an aperture, under a pressure of sixteen feet perpendicular height, it will move at the rate of thirty-two feet in a second; the velocity of the water from the cock F will be nearly as much, making some allowance for friction and resistance; and although the aperture of the cock F is not equal to the diameter of the pipe D, yet the velocity of the water contained in the pipe will be very considerable; consequently when the cock is opened a column of water two hundred yards in length is put into motion, and if it is suddenly stopped by the shutting-cock F, its momentous force will open the valve *g*, and condense the air in vessel H; this action will be repeated as often as water is drawn from F. It is needless to say in what degree the air is thus condensed in the instance before us; but it will be sufficient to observe, that it was so much condensed as to force the water up into the reservoir K, and even to burst the vessel H, in a few months after it was first constructed, although it was apparently very firm, being made of sheet-lead, about nine or ten pounds weight to a square foot. Whence it is reasonable to infer that the momentous force is much superior to the simple pressure of the column in the reservoir K, above the level line CB, and therefore equal to a greater resistance (if required) than a pressure of four or five feet perpendicular height. It may be necessary farther to observe, that the consumption of the water in the kitchen-offices is very considerable, because water is frequently drawing from morning till night all the days of the year.

From this account which is published in the Philosophical Transactions for 1775, it is clear that Mr. Whitehurst was fully aware of the power of the momentum of running water, and though he applied it only to raise water to a small height, he knew it might be carried to a greater extent.

Montgolfier's Hydraulic Ram.—We have given the account of Mr. Whitehurst's machine, because it shews the first origin of a most valuable invention, which was afterwards practised in France by M. Montgolfier, the inventor of the first balloon with heated air. Mr. Boulton took a patent in England for Montgolfier's machine in 1797; he afterwards called his machine *belier hydraulique*, that is, hydraulic ram, because of the shock which the water makes when its motion is suddenly stopped. In his publication in the Journal des Mines, vol. xiii. he says, "This invention is not originally from England, but belongs entirely to France; I declare that I am the sole inventor, and that the idea was not furnished to me by any person. It is true that one of my friends, with my consent, sent to Messrs. Watt and Boulton copies of several drawings of this machine with a detailed memoir on its applications. These are faithfully copied in the patent taken out by Mr. Boulton in England, dated December 13, 1797, as that gentleman has avowed." We do not wish to detract from the merit of M. Montgolfier, as we believe that Whitehurst's machine was unknown to him, but we must state the hydraulic ram an English invention. To have an idea of this invention, it is proper to state its physical principle of action, which is as follows.

When water is running with a rapid current through a pipe or close channel, if the end at which the water issues be suddenly stopped, the water (by its acquired motion, momentum, or impetus,) will act upon the sides or circumference of the pipe, and endeavour to escape with a force proportioned to its quantity and velocity. If the materials of the pipe are strong enough to resist that impetus, the water may be made to issue with violence and velocity, at any aperture which is opened in or near the close end of the pipe; therefore if an ascending pipe be joined to that aperture, a portion of water will ascend in it. The machine being provided with proper valves, to prevent the return of the water so elevated, the operation may be repeated in a constant succession, and will form a kind of perpetual pump.

The same effect will be produced by a different arrangement of this apparatus, *viz.* a pipe open at both ends, with a valve and ascending-pipe, such as has been described. Let this be so attached to some kind of machinery, that it can be swiftly moved along, in the direction of its length, through standing water; then, upon closing the hinder part of the pipe suddenly, a portion of water will be forced up in the ascending-pipe, in the same manner as in the former case, and for the same reason, because the water will be relatively in motion with respect to the pipe.

The same principle may be readily extended to raise water by suction from a lower level than that on which the machine is placed, and this by either of the means above-mentioned. Suppose a suction-pipe, which communicates with water at a lower level, be joined to the main-pipe through which the water flows, and that the junction is near that end of the pipe where the water enters into it. Suppose also that the water has acquired a rapid motion through the pipe, either by the current of water running through the pipe, or by the pipe moving through the water; then let the mouth or end at which the water enters be suddenly shut by the machinery, and the water by its momentum will continue its motion relatively to the pipe, and will tend to exhaust the content of the pipe. This action will draw or suck up water through the ascending-pipe from the lower level, so as to fill up the vacuity in the main-pipe, occasioned when the water therein perseveres in its previous motion.

WATER.

The first and most simple hydraulic ram is shewn in section at *fig. 4.* (*Plate Water-works*); here C C represents the main-pipe, or body of the ram, through which the stream of current water is conducted; D, the ascending-pipe provided with a valve of exit at A, to allow the passage of the water which is raised, but to prevent its return; B is a stop-valve to close the end of the main-pipe; E is a balance-weight fixed upon the lever G, which communicates with another, K, attached to the axis of the stop-valve B; this weight tends to open the valve at the proper time. The main-pipe is to be situated in a current or stream of water, either produced by the natural current or declivity of a river or other stream, or by penning up the water by a dam or weir, and inserting the end of the main-pipe through the dam, so as to obtain the greatest fall of water which the natural circumstances will admit of. To put the machine in action, let the stop-valve be opened to the position shewn in the figure, the water will run through the main-pipe C, until it acquires a certain velocity which will be proportioned to the height of the fall of water which produces the current of water. The action of the current upon the stop-valve B, in its reclined position, will increase until it is sufficient to overcome the weight E, and then it will shut the stop-valve. The water being now suddenly stopped, and confined in the pipe C, by its impetus or momentum, will exert a considerable force within the pipe, which will open the other valve A, and a portion of the water will rise up the ascending-pipe D. The force of the momentum being expended in raising this water, the water in the main-pipe will immediately recover the equilibrium, and the closing of the valve A will prevent the return of the water which is raised in the ascending-pipe. The weight E now descends, and opens the stop-valve B, and the water in the main-pipe resumes its motion until its velocity is sufficient to close the valve A again, and the operation of raising the water is again repeated.

This water gradually rises in the ascending-pipe until it reaches its summit, and then a quantity will issue from it at every stroke into a proper reservoir R. The quantity will be more or less, according as the height to which it is raised, and to the velocity of the current, and the size of the apparatus. In this description, we have taken no notice of the action of the air-vessel J, at the bottom of the ascending-pipe D, although its use is very important to the practicability of the contrivance; for where the water is to be raised to any considerable height, the pipes, although formed of the best materials that can be procured, will be in danger of rupture from the great concussion of the water when suddenly checked; hence the rising of the water would be limited to the height of a few feet, or the pipes must be made of an extraordinary thickness, disregarding expence.

This danger of bursting the pipes is to be regarded in every case of applying this invention to practice; but it will be prevented, or very much diminished, by introducing an air-vessel I. The water from the main-pipe enters at every stroke through the exit-valve A, and compresses the air in the vessel J, which again, by its expansion or elasticity, acts upon the water, (which is prevented from returning to the pipe C by the shutting of the exit-valve,) and therefore rises through the ascending-pipe, and by repeated strokes acquires the desired height.

The dimensions of the air-vessel, as well as its form and position, and whether it is affixed to the main-pipe laterally or above, are in a great measure arbitrary; but its contents of air ought not to be much less than ten times the quantity of water to be raised through the ascending-pipe at each

stroke, and if very much larger still the better, the principal boundary being expence.

The regulation of the stop-valve B, is a principal point in the construction of these machines. It may be opened and shut by the current, as has been described, in a very simple manner, by adapting the valve to move upon an axle or hinge, and assisting it to open at the proper time by a weight attached to a lever fixed to its axis at the proper angle. The valve should be prevented from opening to such a degree, that the action of the current of water could not shut it. This must be done by some fixed resistance behind the valves, as shewn at B, *fig. 3.*, or by any other convenient means.

It is necessary to adjust the weight by experiment, so as to open the valve at the right time, according to circumstances, which may be done either by sliding the weight nearer to, or farther from, the centre of motion, or by increasing or diminishing the weight itself. The inconvenience of this method is, that the weight being generally under water, it is troublesome to adjust it; therefore the mechanism shewn in *fig. 4.* is better adapted to the stop-valve. The weight E is fitted upon a lever connected with a spindle, to which another arm or lever G is also fixed, and that is connected by rod *a*, with the arm K fixed to the valve.

The rod may be prolonged to any necessary length, and the weight and its mechanism may be always placed above water, so as to be easily come at for adjustment. Valves of this kind may be hinged either upon their lower or upper edge, or upon one of the perpendicular sides as a common door, as convenience requires, and the mechanism is connected accordingly.

When it is required to open the stop-valve so completely that the current of water in the main-pipe cannot act upon it, to shut it, a small stream of water is led from the head, which supplies the main-pipe, or from some other source into a pipe or trough, which is furnished with a cock to regulate the quantity. This pipe or trough pours its water into the bucket G, *fig. 5.*, which causes the bucket to preponderate, and by means of the lever *bc*, fixed to its axle, and the rod *cd* attached to it, it shuts the stop-valve B, by the connection of the lever *de* attached to it. The bucket then empties its water, and the pendulous weight E, as soon as the recoil of the water in the main-pipe takes place, preponderating in its turn, opens the valve, and restores the bucket to its place. In this contrivance, by opening the cocks of supply more or less, and by adapting the capacity of the buckets in proportion to the weight E, the number of strokes to be made in any given time is regulated.

The stop-valve may be constructed in a circular form, and, instead of being hinged upon one side, may be fixed upon a spindle in its centre, which slides in a socket, similar to what are called button-valves used in pump-work, and at the proper time is opened by mechanism similar to the former; or, in place of the weight, a spring may be employed.

In constructing large machines, where the shock, from shutting the stop-valve, might endanger the derangement of the machine, other kinds of stop-valves will be preferable to those before described.

A very good form of valve is that which opens in two leaves, like the gates of a canal-lock. The leaves may shut one upon another in the middle, or may shut upon an upright bar placed there. They are opened by the same kind of mechanism as we have described before, only there must be two connecting-rods, one to each leaf of the valve; and these

these being united together, will cause them to shut both together. The aperture for this valve is of a rectangular form.

A valve in two leaves, such as is called a butterfly-valve, may also be hinged in the middle of the opening, but would too much obstruct the water-way. When the main pipe is of a large diameter, (for instance, two feet or upwards,) the stop-valve may be made in three, four, or more leaves connected together by mechanism, similar to Venetian window-blinds.

Another kind of valve is poised upon an axis, like a common fire-stove chimney damper; the axis does not pass through its centre, but divides it into two unequal segments. The valve is not opened so far as to stand in the line of the current of water, but, when opened, stands inclined to that current; so that the larger segment being placed towards the stream, the latter may by its action shut it at the proper time. It is opened by mechanism similar to the former. Another kind of valve is a spherical ball of porcelain, which is fitted into a seat.

When the machine is made use of in an open river, which does not admit of having its water penned up by a weir or dam-head, the main pipe ought to be laid so as to be covered by the low waters of the river; and it ought to be parallel to the surface of the river, so as to have the greatest possible declivity that can be obtained in the length of the main pipe: its mouth or receiving end should be shaped like that of a trumpet or bell. In all cases whatsoever, the valves ought to be completely under the surface of the water, in the lower reservoir.

*Performance of the hydraulic Ram, (see RAM).—*M. Montgolfier, in his publication, says, that a belier hydraulique, executed with care, is capable of rendering three-fourths of the force which is employed to move it, that is, the product of the weight of water raised, multiplied by the height to which it is raised, will be equal to three-fourths of the product of the weight of water which works the machine, multiplied by the height of the fall. Commonly it yields six-tenths, but he would only engage to furnish half. Thus, if the water was to be raised 100 feet by a fall of 5 feet, he would engage to make a machine which should deliver at 100 feet a fortieth part of the whole quantity which fell. He recommends particularly that the machine should be fixed in the most solid manner, by masonry or timber, so that the shock of the water can produce no motion of the machine, because all such motion will deduct considerably from the quantity of water raised. It is stated that the machine will make from 20 to 120 strokes *per* minute.

The dimensions of an hydraulic ram at the bleaching works of M. Turquet, near Senlis, in France, when reduced to English measure, are as follow: diameter of the body of the ram 8 inches, fall of the water 3 feet 4 inches, height to which the water is raised 15 feet 1 inch. In three minutes this machine made 100 strokes, which expended 67 cubic feet of water, and raised $9\frac{1}{4}$ cubic feet: hence, $67 \text{ cubic feet} \times 3\frac{1}{4} \text{ feet} = 223$, and $9\frac{1}{4} \text{ cubic feet} \times 15\frac{1}{7}$

feet = 140. Now $\frac{140}{223}$ is equal to $\frac{6.3}{100}$ ths, so that the

effect produced is above six-tenths of the power applied. In another experiment it was found to be 64-hundredths. This machine raised a quantity of water equal to 6.2 inches of water (pouces de fontanier), for 269 litres which are nearly equal to 280 pints, in three minutes; and the pouce de fontanier is a measure of running water equal to 14 pints (French) *per* minute, or 796.37 cubic inches, English. This ma-

chine working 24 hours will raise 134400 pints (French), or 4512 cubic feet English, of water to a height of 15 feet 1 inch. The water raised by this machine is equal to $\frac{3}{4}$ the power of a man, according to our standard.

M. Montgolfier recommends the pipe or body of the ram to be of an equal diameter through the whole length; and all internal irregularities are to be avoided, because they diminish the velocity of the water: the strength of the pipe should be at least equal to sustain a column of twice the height to which it is intended to raise the water.

He says, that he executed one with a fall of 10 feet, which compressed the air in an air-vessel to an equal degree with 40 atmospheres, which, taking the pressure of the atmosphere equal to 33 feet of water, makes the pressure equal a column of water 1320 feet in height.

Improved hydraulic Ram.—M. Montgolfier, the son of the inventor, has recently obtained a patent in England for an improved hydraulic ram, in which, by attention to some minute particulars in the construction, he is enabled to make the length of the tube much less than in the former machines; and he has even obtained a result equal to 84 *per cent.* of the power employed.

One of these improvements is the addition of a small snifting-valve, which, at each movement, serves to introduce a small quantity of air into the head of the ram, from whence it is driven by the next movement into the air-vessel, which would otherwise become filled with water, if the air, absorbed by the contact of the water under a strong pressure, were not continually replaced by some such means.

Also, in the interior of the head of the ram is an annular space, furrounding the frame of the stop-valve: this contains a small volume of air, which cannot be forced into the air-vessel, but which, at each movement, is compressed by and receives the first effort of the moving water. This he calls the air-matras, and by means of it, the shutting of the stop-valve makes less noise, the pipe is not strained, and all the operations take place with so much ease, that the machine is less shaken, and less frequently out of repair. The following is a description of the new machine.

That end of the pipe or body of the ram which receives the water of the reservoir is formed like a trumpet-mouth, that the water may flow more readily into the pipe; and the length of the pipe must be regulated according to the height of the fall of water, which is to produce the current through it. The pipe is composed of several pieces or lengths screwed together by flanges, or other similar means; but it is in the end piece, which is called the head of the ram, that the moving parts of the machine are placed.

The extremity of the pipe or head of the ram is a hollow sphere, the diameter of which is nearly twice as great as the bore of this pipe: the upper part of the spherical end is flattened, so as to reduce it to a segment of a sphere, with a flat circular surface on the top or upper side, in the centre of which surface is a large circular opening to receive and hold the seat of the stop-valves, at which the water issues; but when the valve is closed, it prevents the water from issuing.

When the valve opens, it descends perpendicularly into the hollow sphere, and leaves a free passage through the opening. Its motion is guided between three or four perpendicular stems, which have hooks formed at the lower ends to retain or support the valve when opened; and these stems are fixed by screws, so that they can be regulated to allow the valve to descend more or less, and open a greater or less passage for the water. The valve is made of metal, and hollow, for it has a flat circular plate of metal, with a hollow cup or dish of metal attached to its lower surface:

this at the same time renders the valve lighter in the water, and gives it a convex surface on the lower side, which, when the valve is opened, corresponds in curvature with the interior concave surface of the spherical end of the head of the ram. The seat of the valve is composed of a short cylinder or pipe, of which the opening is much greater than the transverse section of the body of the ram. This short cylinder is screwed by its flanch into the opening in the upper surface of the head of the ram. This flanch of the seat is so formed as to have an inverted cup round the upper part of the short cylinder, that is, a circular channel or annular space within the head of the ram, which will contain air, and from which the air cannot escape when the water compresses. The air in this channel is called the air-matras.

The snifting-valve is at the end of a small pipe, which leads from the annular space or matras to the open air. The snifting-valve opens inwards, in order to admit the air to enter into the matras; but to prevent its return, there is another small valve in the same pipe, which opens outwards: the office of this is to admit a certain quantity of air into the matras, and then to shut and prevent any farther entrance.

On the outside of the seat of the stop-valve that is over the aperture in the head of the ram, where the water issues, another stop-valve is applied, which is similar to the internal valve before mentioned, but shuts down on the outside of the seat. Its use will be hereafter explained.

The upper part of the pipe or head of the ram is made flat at the part near the end where it enlarges to a sphere; and this flat surface on the top of the pipe has several narrow openings across it, which are covered by as many flap-valves of leather, to allow water to pass out from the main pipe, but to prevent its return. And on each side of the head of the ram, at the part opposite to these flap-valves, is a hollow enlargement, in form of a segment of a horizontal circle; and the two enlargements taken together form a circular basin, through the centre of which the pipe of the ram passes; but, as before stated, the pipe, instead of being circular, is flat at top at that part, to form the seats for the flap-valves. This circular basin is covered by a cylindrical air-vessel, screwed down by means of a flanch at the edge, so that the circular basin forms the bottom of the space in the air-vessel; the flap-valves being covered by the air-vessel are therefore within the vessel.

In consequence of this arrangement, all the water which issues from the body of the ram through the flap-valves will flow off on each side, and be received in the basin; but as the circular basin or bottom of the air-vessel is divided into two parts, by the pipe of the ram which passes through it, there is a passage communicating from one of the enlargements to the other; for which purpose, it curves down and descends beneath the pipe of the ram; and the ascending pipe that carries away the water which the machine raises, proceeds either from this curved passage or from some other part of the basin, so that it may receive the water which has passed from the body of the ram through the flap-valves and the air-vessel into the basin, at each side of the pipe.

The action of this hydraulic ram is nearly the same as the preceding. Suppose the pipe or body of the ram is full of water, if the internal stop-valve is opened, the water from the reservoir will flow through the body of the ram, and issue through the opening at the end, it will lift up the external stop-valve and escape; but the current having continued until the water has acquired a certain velocity, the force of the current buoys up the internal valve, and closes

the passage. The motion of the water contained in the ram will thus be suddenly arrested, and by its *vis inertia*, or moving force, will exert a sudden pressure against the stop-valve, and against all the interior parts of the ram. The small quantity of air contained in the space around the interior stop-valve, which is called the air-matras, is compressed into a smaller space, and, by its elasticity, takes off the violence of the shock or blow which would otherwise be produced. This pressure opens the flap-valves on the top of the pipe, which are within the air-vessel, and a portion of the water will be driven into the air-vessel, which is supposed to be full of air, compressed or condensed, till its elasticity equals the pressure of the column of water which is to be raised up the ascending pipe by the action of the machine.

The water which is forced into the air-vessel causes the air therein to be condensed, and to exert a greater degree of elasticity, until it will exceed the pressure of the column of water in the ascending-pipe; by degrees this air will therefore force through the said pipe all the water which was injected through the flap-valves, and cause that quantity of water to issue from the upper extremity of that pipe.

The moving force, or *vis inertia* of the mass of water, which was in motion in the body of the ram, having expended itself by forcing a portion of water into the air-vessel, and making a still greater compression of the contained air, a recoil of the water in the body will take place with a slight motion from the valve towards the open end of the body; this arises from the reaction or elasticity of the air contained in the air-matras, and also of the metal of which the tube is composed.

The flap-valves within the air-vessel shut, and prevent the return of the water which has been forced into the air-vessel. This recoil of the water in the body towards the open end causes a slight aspiration within the whole body of the ram, and the external stop-valve descends by its weight, and prevents the water with which it is covered from entering through it; but the air passes through the small pipe, leading from the open air to the annular space or air-matras, and opens the snifting-valve, and a small quantity of air is sucked into the matras; but this is a very small quantity, because the external air-valve closes as soon as the air flows with a rapid current through the pipe and snifting-valve.

During the recoil, the internal stop-valve having nothing to sustain falls by its weight, and opens the passage; and as soon as the force of the recoil has expended itself in acting against the column of water contained in the reservoir at the open end of the body, the water begins again to flow through the body in its original direction, and repeats the action before described.

It shuts the internal stop-valve when it has acquired the intended velocity, and being thus stopped, the efflux of the *vis inertia* condenses the air-matras, and opening the flap-valves, forces a quantity of water into the air-vessel, from which the reaction of the contained air will drive it up the ascending-pipe.

The *vis inertia* of the moving column of water being thus expended, the recoil commences by the reaction of the air in the matras, the flap-valves shut, and the external stop-valve likewise; the aspiration produced by the recoil draws some air through the snifting-valve, and it joins the air in the matras. The internal stop-valve falls open by its weight and opens the passage, so that the water in the pipe can resume its motion when the recoil has exhausted itself.

The small quantity of air which is drawn into the machine through the air-valve, at each aspiration, causes an accumulation

cumulation of air in the matrafs; and when the aspiration of the recoil takes place, a small quantity of this air passes from the annular space, and proceeds along the pipe till it arrives beneath the flap-valve, and lodging in the small space beneath these valves, it will be forced into the air-vessel at the next stroke, by which means the air-vessel is always kept filled with air.

The following are the dimensions of a machine which is calculated to raise water up the tube to 100 feet above the surface of the water in the reservoir, when the fall by which it is worked is five feet, that is, where the level of the water in the reservoir is five feet above the lower level; and the length of the pipe from the open end to where the water is discharged is to be twenty feet long, and six inches in diameter.

Such a machine may be expected to expend about seventy cubic feet *per* minute to work it, and to raise up about two and one-third cubic feet *per* minute; but these quantities cannot be exactly stated, because they depend upon the care and accuracy with which the machine is constructed. Under different circumstances, having a greater or less fall or quantity of water, the dimension of the machine must be calculated accordingly.

The improvements in this last form of the hydraulic ram are,

First, that by constructing the head of the ram with the upper side of the pipe flat, and applying the flap-valves immediately upon the top, there is very little space to contain dead water, that is, water which will be motionless when the current takes place in the pipe; and by dividing the single valve of the original machine into several small and narrow valves, they open and shut more suddenly, and with less loss of water.

Secondly, in making the basin on each side of the pipe, which basin is on a lower level than the flap-valves. By this means the water will flow off from the flap-valve on each side, and at the instant when the machine performs its stroke, and forces water through the said valves into the air-vessel, the valves will not be covered, or at least very slightly covered by water; consequently, when those valves open, and the water is forced into the air-vessel, it has only the compressed air to oppose it, which from its elasticity allows the water to enter with more facility than if it was resisted by a column of water resting upon the valves; not that there is any less hydrostatic pressure upon the valves, because it is the air which bears upon them, instead of the water, but there is a less mass of matter to be put in motion by the water which enters into the air-vessel: for it has only the matter contained in the valves themselves to put in motion.

Thirdly, in applying the external stop-valve, the use of which is to prevent the water returning into the ram when the recoil takes place, and having this provision, a greater quantity of air can be employed in the matrafs than could otherwise conveniently be done; this renders the shock which takes place when the stop-valve is shut less sudden. We have examined several of these machines made in France by the inventor, and can with confidence recommend them to engineers as the very best machine, and the most simple for raising water when there is a natural fall. The last improvements, as they enable us to shorten the length of the body of the ram to nearly one-third, without reducing the performance, are very important.

The hydraulic ram is adapted to give motion to the hydrostatic presses, which are in common use under the name of Bramah's presses. For this purpose, it is only necessary to apply the ascending-pipe to the cylinder of the hydraulic press, and at each stroke of the ram a small quantity of

water will be forced or injected into the cylinder of the press, and will thus produce the ascent of the piston of the press in the same manner as is now performed by the small injection-pump worked by the force of men. But by the application of the hydraulic ram to that purpose, the press can be worked in any situation where there is a small fall of water, and the ram may be set in motion whenever the press is wanted.

An *Hydraulic Ram*, or *Momentum Machine acting by Suction*, is shewn at *figs. 2 and 3, Plate Water-works*. This is applicable in cases where the water to be raised is below the level of the main-pipe, and is to be discharged at that level; a case which frequently occurs in the drainage of marshy lands, where the action of the current of water, in an embanked river, or other stream or source of water on a higher level, can be employed; or this method can be applied in raising water out of the holds of ships by the motion of the vessel through the water; also to raise water out of a well of moderate depth.

C represents a portion of the main-pipe; B, *fig. 2* is the stop-valve situated at the entrance of the pipe, and opening outwards so as to stop the passage of the pipe when it is shut; D, the ascending or sucking-pipe, communicating with the well at the bottom and with the main-pipe at the top; J is the air-vessel; and E the weight of the stop-valve of the main-pipe. There is likewise a valve A opening from the air-vessel into the main-pipe.

The water in the main-pipe having acquired a proper velocity by the current, as in the former cases, the stop-valve B shuts, and the water in the main-pipe continuing its motion for a time, draws air out of the air-vessel J, through the valve A. The momentum of the water in the main-pipe being soon expended it recoils, the receiving-valve A shuts to prevent the return of the water into the air-vessel, and the stop-valve B opens by the action of the weight E, the water thus regains its passage, and soon acquires sufficient velocity to close the stop-valve again, and the operation is repeated.

Thus in a few strokes the exhaustion is increased till the air-vessel sucks up water from below, through the ascending-pipe D, or rather the pressure of the atmosphere on the surface of the valve below forces it up, when the pressure on the surface within the air-vessel is removed by the exhaustion. This action being continued, the ascending-pipe fills by degrees to the top, after which, at every successive stroke, a portion of the water from below passes into the main-pipe, and is carried off into the pipe C, where it mixes with the upper water.

In cases where the water of the tide or other alternating current is employed as the motive power, the apparatus may be constructed in two ways, either by applying a stop-valve, air-vessel, and ascending-pipe, such as is shewn at one end in *fig. 4*. to each end of the main-pipe C, to be used alternately, according as the tide sets in the one direction or the other; or otherwise by applying two main pipes to one air-vessel, their mouths being placed in opposite directions and to be used alternately, and applied to the raising of water, for the use of salt-works, or for other uses, such as the supply of a country-house.

The first machine above described may be employed to raise water to small heights by the motion of the waves of the sea, or of any large pieces of water; in which case the mouth or receiving end of the main-pipe should be formed like a speaking-trumpet, as shewn in *fig. 4*. and placed opposite to the direction in which the waves beat upon the shore at the place where the machine is. The water of the waves will enter the main-pipe, and rush through it until the

the stop-valve shuts; when the contained water will in part enter the air-vessel by the action already described, and the next wave will produce another stroke.

Momentum-Pump, or Momentum-Machine, to raise Water by the Application of mechanical Power.—Where a fall of water cannot be obtained, *fig. 1.* shews an application of this momentum principle, in lieu of pumps for raising water, the main-pipe being put in motion through the water by the strength of men, or other mechanical power in default of a current, as in the other cases.

CC is the main-pipe bent in a spiral form round the air-vessel J; it may either be made to touch it, or be kept at a distance from it, and may make one or more revolutions round the said vessel; the whole of the main-pipe is immersed in the external water which is to be raised. Both ends of the pipe are open to the water; but one of them has the stop-valve opening inwards, which will occasionally close it, and near this latter end, a communication is made by a side-pipe with the air-vessel, the orifice being covered by a valve opening into the vessel. The whole turns upon a pivot K, at the lower end of the ascending-pipe D, which serves as an axis, and is kept upright by a collar, in which it turns, as shewn at L. Upon this axis a toothed wheel M is fixed, and is put in motion by another wheel N, turned by a winch, crank, or other contrivance.

At the top, or upper end of the ascending-pipe, the water is discharged into a trough, which surrounds it, and conveys it to the place of its destination.

This apparatus is made to raise water by a continued rotatory motion, the open end moving first, through the water which passes out again through the other end; but whenever, by that motion, the main-pipe has attained a proper velocity, the stop-valve shuts suddenly, and by the concussion the water passes into the air-vessel, from whence the egress of the water is prevented by the shutting of the exit-valve. The stop-valve then opens by means of a spring in lieu of a weight, as in the former cases, and the apparatus continuing to revolve in the same direction, more strokes are made at intervals proportioned to the velocity with which it moves. The spring of the stop-valve should be so regulated in force as to allow the relative motion of the water in the main-pipe to shut the stop-valve at proper intervals. The perpendicular section of the main-pipe is drawn square, but may be circular, or of any other convenient figure. A horizontal section of it is shewn at *fig. 6.* with the main-pipe and the air-vessel.

In lieu of the wheel N, which produces a continued rotatory motion, the machine may be made to vibrate or swing upon an axis, backwards and forwards, the limits of the vibration or stroke being determined by a detent striking against a stiff spring. In this case, the main-pipe should be provided with stop-valves at both ends, and also have a communication at each end with the air-vessel, which openings should be closed by valves to prevent the return of the water from it. Such a machine may be put in motion by the following means: upon the ascending-pipe D, a double pulley is fixed, round which are wound the ropes, and by pulling the ends of these alternately, the apparatus may be made to revolve in either direction. The main-pipe and the ascending-pipe being filled with water by hand or otherwise, if the ropes are pulled alternately, they will make the pipe move through the water with sufficient velocity to make the apparatus act. It is found if the apparatus makes about thirty vibrations in each minute, that it will act very completely.

Hydraulic machines are of the greatest importance to society, whether we look to a supply of the first necessity

for domestic uses, or to the advantageous uses of neglected though valuable first movers. These machines must, in most cases, be modified by localities, and other circumstances; and consequently the most useful practical knowledge will not consist in any acquaintance with one or more of the best engines, but with that great variety of happy contrivances which inquiry and reflection must point out. We have, as far as our limits permit, given all the machines which are practically useful, and we shall conclude this article by giving Dr. Young's catalogue of the most important and valuable writings on hydraulic engines.

A short account of the invention, theory, and practice of fire-machinery; or introduction to the art of making ma-

chines, vulgarly called steam-engines, in order to extract water from mines, convey it to towns, and jets d'eaux in gardens, to procure water-falls for fulling, hammering, stamping, rolling, and corn-mills, by William Blakey, 1793. Egerton.

Machines actuated by the Force of Currents or Streams of Water.—These are very numerous, but all may be reduced to two kinds.

First, those which are adapted to receive the impulse of moving water; that is, water which has been put in motion in consequence of a descent towards the earth previously to its operating on the machine, which must be provided with parts proper to resist and take away some of the motion of such water, and it will thereby receive motion which may be applied to produce some mechanical effect. Of this kind are undershot and horizontal water-wheels.

Secondly, those machines which are provided with some kinds of buckets or vessels to contain water, the weight of which buckets, and the water they contain, is supported by the machine, so that the water cannot descend towards the earth in consequence of its gravitation, without giving motion to the buckets or vessels which contain and support it. Of this kind is the over-shot water-wheel, breast-wheel, chain of buckets, and pressure-engine.

In either case, the motive force or power is the same; viz. the gravitation and motion of such bodies or masses of water as are found more elevated above the surface of the earth than the general level of the sea, or of some other water in its neighbourhood; such water will descend by the force of gravity until it joins the sea, or until it is supported or held up by some fixed obstacle.

The difference between the two kinds of machines is, that in the first case the water is suffered to descend before it operates upon the machine, and in consequence of its gravitation, acquires motion with a velocity proportioned to the space through which it has descended; and the office of the machine is to take from the moving water as much of its compounded weight and motion, or power, as it can obtain.

In the other case, the machine receives its motion and power at the same time, when the water acquires it, by descending; or, in other words, the machine moves with the water.

The word *power*, as used in practical mechanics, signifies the exertion of strength, gravitation, impulse, or pressure, so as to produce motion; and a machine actuated by means of strength, gravitation, impulse, or pressure, compounded with motion, is capable of producing an effect: and no effect is properly mechanical but what requires such a kind of power to produce it.

The muscular power of animals, as likewise pressure, impact, gravity, electricity, &c. are looked upon as forces, or sources of motion; for it is an incontrovertible fact that bodies exposed to the free action of either of these are put in motion, or have the state of their motion changed. All forces, however various, can be measured by the effects they produce in like circumstances; whether the effects be creating, accelerating, retarding, or deflecting motions: the effect of some general and commonly observed force is taken as unity.

The most proper measure of power is the act of raising some weight with some velocity of motion; that is, the overcoming of the gravitating force of a weight in such degree as to produce motion in opposition to gravity. In considering the quantum, the weight or mass of matter operated upon must be one quantity, and the velocity of the motion communicated is the other; the mechanical power is the

the compound of both. We can only measure the weight of any body or mass of matter by its relation to some other weight with which we are acquainted; hence we say, the weight is equal to so many pounds, or so many cubic feet of water. In like manner, we measure the velocity or intensity of the motion, by stating the height or perpendicular distance from the earth, (measured by relation to some known distance, as a foot or a yard,) through which height the weight is raised in some known space of time, as a second or a minute.

For instance, 528 cubic feet of water is a known weight or mass of water: let a machine operate upon this, and raise it upwards, through the space of one foot in the time of one minute; then $528 \times 1 \times 1 = 528$ is the number which represents the power which the machine exerts. Suppose another machine to operate on 132 cubic feet of water, and raise it four feet in one minute, then using the same measures to determine the quantities of weight, height, and time, we say $132 \times 4 \times 1 = 528$; hence these two machines are equal in the power which they exert; for in all cases the weight raised is to be multiplied by the height to which it can be raised in a given time, and the product is the measure of the power expended in raising it; consequently, all those powers are equal whose products made, by such multiplication, are equal; for example, take two powers, if one can in any given time raise twice the weight to the same height, or the same weight to twice the height, in the same time that the other power can, the first power is double the second; or, if one power can raise half the weight to double the height, or double the weight to half the height, in the same time that another can, those two powers are equal: but note, all this is to be understood only in cases of slow or equable motion of the body raised, for in quick, accelerated, or retarded motions, the *vis inertia* of the matter moved will make a variation.

The machines actuated by the impulse of flowing water are, the undershot water-wheel, horizontal wheels, and Dr. Barker's mill. It is a common expression to call all wheels in which the water runs or shoots under the wheel, undershot; but in this place we shall only speak of

Undershot Water-Wheels, acting by the Impulse of flowing Water.—These are the most ancient and original forms of water-machines, although if they had been invented from the result of reasoning, such as we have given, they would have been the last, because their manner of action is less obvious; but this was not the case. The first machines were wheels placed in a river or running stream, and provided with vanes or wings on the circumference, called floats; the floats at the lower part of the wheel, dipped into the stream to intercept the water. When the plane of the floats became perpendicular to the direction of the current, or nearly so, they would resist or oppose the motion of the water, and the wheel would obtain motion from it in proportion to the quantity of motion, its floats abstracted from the water of the stream. The power thus obtained would be found to be only a small proportion of the power of the stream, because the water would easily escape sideways from the floats, particularly if it were attempted to take away any considerable share of the velocity of the water, by resisting or loading the wheel, so as to make it move slowly. Hence it became an obvious improvement to contract the river to the exact size of the float-boards of the wheel, or to make a close channel in which the wheel exactly fits. The next improvement would be to intercept the river or stream of water by a dam, or obstacle, in order to make it pen up, or accumulate, till it had risen to the greatest height which could be obtained, and to let the water out of the dam or

reservoir into the channel or wheel-course, through a vertical aperture or door, level with the bottom of the wheel-course; in this way, the water would be urged by the pressure of the water in the dam, and would rush out from the aperture in a stream or spout, with a velocity proportioned to the perpendicular pressure, and would strike the float-boards of the wheel so as to urge them forwards. Such is the form of the undershot wheels still generally employed in France and on the continent; but in England they have been long superseded by more effectual applications of the power of the water, and it is very rarely we meet with an undershot wheel acting by the impulse of the water. They are called ground-shot wheels, because the water runs or shoots along the ground or floor of the channels in which the wheels work.

It was first proved by Mr. Smeaton, in 1754, that only a portion of the power of any fall of water could be obtained by means of an undershot wheel; for M. Belidor had not long before stated the undershot wheel as the best mode of applying a fall of water. It was one of the continual occupations of Mr. Smeaton, during forty years, to improve the old water-mills, by substituting breast-wheels for undershot; and the advantages were uniformly so great, that these mills were copied by others, until scarcely any of the original construction remained. We do not mean that Mr. Smeaton invented the breast-wheel, for it is described by Leopold; but he first investigated its comparative advantages.

It is from this circumstance that we find, in all the mechanical writings of foreign authors, much more mathematical investigation relative to the undershot water-wheels than the importance of the subject deserves, and we shall dismiss it more briefly.

The excellent paper by Mr. Smeaton, in the Philosophical Transactions for 1759, contains a numerous list of experiments most judiciously contrived by him, and executed with the accuracy and attention to the most important circumstances which are to be observed in all that gentleman's performances.

Mr. Smeaton's rules were originally deduced from experiments made on working models, which are the best means of obtaining the outlines in mechanical enquiries; but in every case it is necessary to distinguish the circumstances in which a model differs from a machine at large, otherwise a model is more apt to lead from truth than towards it; and we must not, without great caution, transfer the results of such experiments to large works. But we may safely transfer the laws of variation, which result from a variation of circumstances, although we must not adopt the absolute quantities of the variations themselves. Mr. Smeaton was fully aware of the limitations to which conclusions drawn from experiments on models are subject, and has made the applications with his usual sagacity. The best structure of machines cannot be fully ascertained but by making trials with them, when made of their proper size.

Mr. Smeaton's Principles for Undershot Wheels.—In comparing the effect produced by water-wheels with the powers producing them; or, in other words, to know what part of the original power is necessarily lost in the application, we must previously know how much of the power is spent in overcoming the friction of the machinery, and the resistance of the air; also, what is the real velocity of the water at the instant it strikes the wheel; and the real quantity of water expended in a given time.

The velocity Mr. Smeaton measured in a most satisfactory manner in every experiment, by applying a cord and weight to the axle of the wheel, not to wind up the weight by the motion

motion of the wheel, but that the weight by descending should turn the wheel. He applied so much weight as would make the wheel turn, and make its floats move with the velocity which he desired or expected the effluent water to have; and this weight he adjusted until he found, by repeated trials, that the wheel moved just at the same rate, whether the water was suffered to flow and strike its floats, or whether the water was stopped, which proved that the floats of the wheel moved with precisely the same velocity as the effluent water; then by measuring the circumference of the wheel, and counting the number of turns it made in a minute, he obtained the measure of the velocity.

From the velocity of the water at the instant that it strikes the wheel, the height of head productive of such velocity can be deduced from acknowledged and experimented principles of hydrostatics; so that by multiplying the quantity or weight of water really expended in a given time by the height of a head so obtained, which must be considered as the effective height from which that weight of water had descended in that given time, we shall have a product equal to the original power of the water, and clear of all uncertainty that would arise from the friction of the water in passing small apertures, and from all doubts arising from the different measure of spouting waters, assigned by different authors.

On the other hand, the sum of the weights raised by the action of this water, and of the weight required to overcome the friction and resistance of the machine, multiplied by the height to which the weight can be raised in the time given, the product will be equal to the effect of that power; and the proportion of the two products will be the proportion of the power to the effect: so that by loading the wheel with different weights successively, we shall be able to determine at what particular load and velocity of the wheel the effect is a maximum.

From experiments conducted in this manner, Mr. Smeaton settled the following maxims:

Maxim 1. That the virtual or effective head of water, and consequently its effluent velocity being the same, the mechanical effect produced by a wheel actuated by this water will be nearly in proportion to the quantity of water expended.

Note. The virtual or effective head of any water which is moving with a certain velocity, is that height from which a heavy body must fall in order to acquire the same velocity.

The height of the virtual head, therefore, may be easily determined from the velocity of the water; for the heights are as the square of the velocities; and the velocities, consequently, as the square roots of the heights. Mr. Smeaton observed the velocity of the effluent water in all his experiments, and thence calculated the virtual head; he states that the virtual head bears no proportion to the real head or depth of water; but that when either the aperture is greater, or when the velocity of the water issuing therefrom less, they approach nearer to a coincidence; and consequently, in the large openings of mills and sluices, where great quantities of water are discharged from moderate heads, the actual head of water, and the virtual head, as determined by theory from the velocity, will nearly agree.

For example of the application of his first maxim. Suppose a mill driven by a fall of water, whose virtual head is 5 feet, and which discharged 550 cubic feet of water per minute; and that it is capable of grinding four bushels of wheat in an hour. Now another mill, having the same virtual head, but which discharges 1100 cubic feet of water per minute, will grind eight bushels of corn in an hour.

Maxim 2. That the expence of water being the same, the effect produced by an undershot wheel will be nearly in pro-

portion to the height of the virtual or effective head. This is proved in the preceding example.

Maxim 3. That the quantity of water expended being the same, the effect will be nearly as the square of the velocity of the water; that is, if a mill driven by a certain quantity of water, moving with the velocity of 18 feet per second, is capable of grinding 4 bushels of corn in an hour, another mill, driven by the same quantity of water, but moving with the velocity of $22\frac{1}{2}$ feet per second, will grind nearly 7 bushels of corn in an hour; because the square of 18 is 324, and the square of $22\frac{1}{2}$ is $506\frac{1}{4}$. Now say, as 324 is to 4 bushels, so is $500\frac{1}{4}$ to $6\frac{1}{2}$ bushels; that is, as 4 to $6\frac{1}{2}$.

Maxim 4. The aperture through which the water issues being the same, the effect will be nearly as the cube of the velocity of the water issuing; that is, if a mill driven by water rushing through a certain aperture with the velocity of 18 feet per second will grind 4 bushels of corn in an hour, another mill, driven by water moving through the same aperture, but with the velocity of $22\frac{1}{2}$ feet per second, will grind 51 bushels; for the cube of 18 is 5832, and the cube of $22\frac{1}{2}$ is 11390 $\frac{3}{4}$; then, as 5832 is to 4, so is 11390 $\frac{3}{4}$ to $7\frac{3}{4}$.

Maxim 5. The proportions between the power of the water expended, and the effect produced by the wheel, was 3 to 1. Upon comparing several experiments, Mr. Smeaton fixed the proportions between them for large works; that is, if the weight of the water which is expended in any given time be multiplied by the height of the fall, and if the weight raised be also multiplied by the height through which it is raised, the first of these two products will be three times that of the second.

Maxim 6. The best general proportions of velocities between the water and the floats of the wheels will be that of 5 to 2; for instance, if the water when it strikes the wheel moves with a velocity of eighteen feet per second, the wheel must be so loaded that its float-boards will move with a velocity of 7.2 feet per second, and the wheel will then derive the greatest power from the water, because as 5 to 18, so is 2 to 7.2.

Maxim 7. There is no certain ratio between the load that the wheel will carry when producing its maximum of effect, and the load that will totally stop it; but it approaches nearest to the ratio of 4 to 3, whenever the power exerted by the wheel is greatest, whether it arises from an increase of the velocity, or from an increased quantity of water; and this proportion seems to be the most applicable to large works. But when we know the effect a wheel ought to produce, and the velocity it ought to move with whilst producing that effect, the exact knowledge of the greatest load it will bear is of very little consequence in practice.

Maxim 8. The load that the wheel ought to have, in order to work to the most advantage, can be always assigned thus: ascertain the power of the whole body of water, by multiplying the weight of the water expended in a minute by the height of the fall, take one-third of the product, and it gives the effect of power which the wheel ought to produce: to find the load, we must divide this product by the velocity which the wheel should have, and that, as we have before settled, should be two-fifths of the velocity with which the water moves when it strikes the wheel.

The wheel must not be placed in an open river to be actuated by the natural current, in which case, after it has communicated its impulse to the float, it has room on all sides to escape: this is the supposititious case on which most mathematicians have proceeded; but in all these experi-

ments, the wheel is placed in a conduit or race, to which the float-boards are exactly adapted, and the water cannot otherwise escape than by moving along with the wheel. It is observable in a wheel working in this manner, that as soon as the water meets the float, it receives a sudden check, and rises up against the float, like a wave against a fixed object, inasmuch that when the sheet of water is not a quarter of an inch thick before it meets the float, this sheet will act upon the whole surface of a float, whose height is three inches; and consequently, where the float is no higher than the thickness of the sheet of water, as theory also supposes, a great part of the force would have been lost by the water dashing over the float.

The wheel which Mr. Smeaton used had originally twenty-four floats, and was afterwards reduced to twelve, which caused a diminution in the effect, on account of a greater quantity of water escaping between the floats and the floor of the channel in which it moved; but a circular sweep being adapted thereto, of such a length, that one float entered the curve before the preceding one quitted it, the effect came so near to the former as not to give hopes of advancing it, by increasing the number of floats beyond twenty-four in this particular wheel.

Mr. Smeaton observes that, in many of the experiments, the results were by different ratios than those which his maxims supposed; but as the deviations were never very considerable, the greatest being about one-eighth of the quantities in question, and as it is not practicable to make experiments of so compound a nature with absolute precision, he supposes, that the lesser powers are attended with some friction or work under some disadvantages, which have not been duly accounted for; and, therefore, he concludes that these maxims will hold very nearly, when applied to works in large.

Application of these Principles to Practice.—The first thing to be done in a situation where an undershot wheel is intended to be fixed, is to consider whether the water can run off clear from the wheel, so as to have no back water to impede its motion; and whether the fall which can be obtained by constructing a proper dam to pen up the water and sluice for it to pass through, will cause it to strike the float-boards of the wheel with a sufficient velocity to impel them forcibly forwards; and also, whether the quantity of the supply will be sufficient to keep a wheel at work for a certain number of hours each day.

When we have ascertained the height of the fall of water, that is, the height of the surface above the centre of the opening of the sluice, we must find what will be the continual velocity of the water issuing out from such opening.

In some cases, we have the velocity of the water given when it issues from the opening of the sluice, and we then require to know what height of column will produce that velocity. These two things we may find by a single rule, and an easy arithmetical operation, which is as follows:

1st. The perpendicular height of the fall of water being given in feet and decimals of feet, the velocity that the water will acquire *per second*, expressed in feet and decimals, may be found by the following rule:

Multiply the constant number 64.2882 by the given height, and the square root of the product is the velocity required.

Example 1.—If the height is two feet, the velocity will be found 11.34 feet *per second*.

Example 2.—If the height is 16,0913 feet, the velocity will be 32,1826 feet *per second*.

Example 3.—If the height is fifty feet, the velocity will be 56,68 feet *per second*.

Note. The velocities thus obtained will be only the theoretic velocity, that is, the velocity any body would acquire by falling through such height *in vacuo*, the velocity in reality will be less, generally six or seven-tenths.

The uniform velocity of a fluid being given, expressed in feet and decimals of feet *per second*, the height of the column or fall to produce such a velocity may be found by the following rule:

Multiply the given velocity into itself, and divide the product by 64,2882; the quotient will be the height required, expressed in feet and decimals.

Example 1.—If the velocity given is three feet *per second*, the height will be 0.139 of a foot.

Example 2.—If the velocity given is 32,1826 feet *per second*, the height will be found 16,0913 feet.

Example 3.—Let the velocity be 100 feet *per second*, the height will be 155,649 feet.

The knowledge of the foregoing particulars is absolutely necessary for constructing an undershot water-wheel; but the most advantageous method of setting it to work, and to find out the utmost it could perform, would be very difficult, if we were not furnished with the maximum which Mr. Smeaton settled, by shewing, that an undershot water-wheel will act to the greatest advantage, when the velocity of its float-boards is equal to two-fifths or four-tenth parts of that of the water which gives it motion.

To illustrate this, let us consider a wheel equally balanced on all sides, and turning freely round upon its pivots, its circumference would soon move as fast as the current it was placed in. Suppose the water to move at the rate of three feet in a second, the circumference of the wheel would pass through three feet in a second. In this case, the wheel performs no work, and the effect produced is nothing.

Now in attempting to apply the power of this wheel to turn any kind of machinery, suppose the work to be so proportioned, that the resistance would cause the wheel to stand still and stop the water, or make it run over the floats, in consequence of its not having sufficient force to carry the float-boards along with it. In this case also, there being no motion, there could be no mechanical effect produced; but if the resistance be diminished by degrees, the wheel would begin to partake of the motion of the current of water, and being loaded, would produce a mechanical effect proportioned to the load and velocity. The wheel would increase in its velocity in proportion as the resistance was diminished, and the mechanical effect would increase also until a certain point when the wheel moved so fast, that the water would not strike the float-boards quick enough to produce the greatest effect: this is found to be as before mentioned, when the floats move four-tenths as fast as the water, because then six-tenths of the water is employed in driving the wheel with a force proportional to the square of its velocity.

If we multiply the surface or area of the opening by the height of the column, we shall ascertain the body or column of water which should press against that float-board, which is immediately under the wheel, supposing it has no motion; but it will be found, that a small proportion of the weight of the original column hung on the opposite side of the wheel, would arrest its motion entirely; but when we would have it to move with a proper velocity, that is, two-fifths of that velocity with which the water moves, $\frac{1}{16} \frac{3}{16} \frac{9}{16}$ of the weight of the original column, is the weight which the wheel would raise with four-tenths of the velocity that the water moves with, and the power which the wheel would exert on the machinery to grind corn, lift hammers, raise water,

WATER.

water, &c. is $\frac{1}{1000}$ of the weight of the water multiplied by $\frac{1}{10}$ of its velocity.

Thus it appears that an undershot water-wheel, constructed after the foregoing manner, would only raise one-third part of the water expended to the same height, as the original head or level. This is the utmost that can be expected, though often less is done; because here we suppose every part exactly performed, and the water applied to the wheel in the best manner; therefore, as we cannot come up to the maximum, we must come as near it as we can by losing the least possible of the power's impulse.

It is no advantage to have a very great number of float-boards round the wheel, because when they are struck by the water, as applied in the best manner possible, the sum of the impulses exerted on the different floats, will but be equal to the impulse made against one float-board struck by all the water issuing from the sluice at right angles to its surface. But as this float-board must move forward, there must be a succession of float-boards to receive the impulse of the water, and since they cannot receive it at right angles, there will be some loss of impulse in that succession. Besides when the first float-board is so far past the perpendicular, as to have the action of the water intercepted by the succeeding one, it is checked by the back water through which it must pass in rising out of the water, and thereby be so far retarded as to take from the full effect of the impulse on the following float. Indeed if all the water could run off immediately after having performed its office, this would not happen; but it can seldom be effected in undershot-mills, especially those built upon rivers. All the remedy in such case is, (when the diameter of the wheel is settled) to fix just such a number of floats upon it, that each one, after it has received the full impulse of the water, may come out of the water as soon as possible, that another succeeding float may be brought to receive the impulse, otherwise the wheel would remain a moment without any impulse.

In the article *MILL* we have given a table for the dimensions and proportions for undershot wheels, which was calculated by Mr. Ferguson. Dr. Brewster, in his new edition of Mr. Ferguson's works, has given an improved table, which is calculated upon the following principles.

It is evident that the water-wheel must always move with less velocity than the water, even when there is no work to be performed; for a part of the impelling power is necessarily spent in overcoming the *inertia* of the wheel itself; and if the wheel has little or no velocity, it is equally manifest that it will produce a very small effect.

There is consequently a certain proportion between the velocity of the water and the wheel, when the effect is a maximum. Mr. Smeaton has shewn the greatest effect is produced when the velocity of the wheel is between one-third and one-half, but the maximum is much nearer to one-half than one-third. He observes also that one-half would be the true maximum, if nothing were lost by the resistance of the air, the scattering of the water carried up by the wheel, and thrown off by the centrifugal force, and the leakages of the water between the floats and the water-course, all which tend to produce a greater diminution of the effect at that velocity, which would be the maximum if these losses did not take place, than they do when the motion is a little slower. The great hydraulic machine at Marly, the wheels of which are undershot, was found to produce a maximum effect when the velocity of the wheel was two-fifths that of the current. Hence Dr. Brewster concludes that in theory the velocity of the wheel is one-half that of the current, and that

in practice it is never more than three-eighths of the stream's velocity, when the effect is a maximum.

Dr. Brewster's Table of undershot Water-Wheels, in which the velocity of the wheel is three-sevenths of the velocity of the water, and the effects of friction on the velocity of the stream are reduced to computation. The wheel is supposed to be fifteen feet diameter.

Height of the Fall of Water.	Velocity of the Water per Second, Friction being considered.	Velocity of the Wheel per Second being three-sevenths that of the Water.	Revolutions of the Wheel per Minute, its Diameter being fifteen Feet.
Feet.	Feet and Decimals.	Feet and Decimals.	Revolutions and Decimals.
1	7.62	3.27	4.16
2	10.77	4.62	5.88
3	13.20	5.66	7.20
4	15.24	6.53	8.32
5	17.04	7.30	9.28

18	32.33	13.86	17.65
19	33.22	14.24	18.13
20	34.17	14.64	18.64

Another Manner of applying Water to an undershot Wheel.—This was proposed by M. Fabre as the result of much mathematical investigation, and has been so frequently recommended by authors of eminence, that we shall give a short description without entering into all his rules for the proportions. The principal difference in this wheel from that in common use is, that the water is made to run down a rapid slope or inclined plane, in order to strike the floats of the wheel, instead of issuing from an aperture or sluice situated beneath the surface of the water in the reservoir. A mill is usually situated at a distance from the river, with a canal or water-course to conduct the water to the mill; as it is of the highest importance to have the height of the fall as great as possible, the bottom of the canal or water-course, which conducts the water from the river to the mill, should have a very small declivity; for the height of the water-fall at the mill will diminish in proportion as the declivity of the canal is increased: it will be sufficient to make it slope about one inch in 200 yards, taking care to make the declivity about half an inch in the first 48 yards, in order that the water may have a velocity sufficient to prevent it from flowing back into the river.

When the water is thus brought to the channel in which the wheel is placed, the water is recommended to be conducted down a slope or inclined plane, making an angle of $64\frac{1}{2}$ degrees with the horizon; that is, in a perpendicular of ten feet, the slope should deviate from it $4\frac{3}{4}$ feet: at the bottom of this slope the water is to be again conducted horizontally, and then to strike the float-boards of the wheel.

wheel. To render the fall of the water easy, the slope is to be rounded off by a convexity at top and a concavity at bottom, to lead the water from the horizontal to the slope, and again from the slope without abruptness. It is supposed that the water, in running down this inclined plane, will acquire the same velocity as if it had fallen perpendicularly through a height equal to the perpendicular height of the slope.

The distance through which the water runs horizontally, from the foot of the slope before it acts upon the wheel, should not be less than two or three feet, in order that the different portions of the fluid may have obtained an horizontal direction; but if this horizontal distance be much larger, the velocity of the stream would be diminished by its friction on the bottom and sides of the water-course. That less water may escape between float-boards and the bottom of the course, it should be formed into the arch of a circle concentric with the wheel, which sweep should be prolonged, so as to support the water as long as it can act upon the float-boards; beyond this sweep should be a step or fall of not much less than nine inches with a slope of about 45 degrees, that the water having spent the greater part of its force in impelling the float-boards, may not accumulate below the wheel and retard its motion. After this step the course of discharge, or tail water-course to run off the water from the wheel, should be floored with wood or masonry about 16 yards long, having an inch of declivity in every two yards.

The canal which conducts the water from the course of discharge to join the river again, should slope about four inches in the first 200 yards, and three inches in the second 200 yards, and so decreasing gradually till it terminates in the river. But if the river to which the water is conveyed, should be subject to be swollen by the rains, so as to force the water back upon the wheel, the canal must have a greater declivity, in order to prevent this from taking place. Hence it will be evident, that very accurate levelling is necessary for the proper formation of the mill-course. The tail water-course ought always to have a very considerable breadth, which should be greater than that of the wheel-race, or part in which the wheel acts, that the water having room to spread may have less depth. The section of the fluid at the point where it strikes the wheel should be rectangular, the breadth of the stream having a determinate relation to its depth. If there is a great stream of water, the breadth should be triple the depth; if there is a moderate quantity, the breadth should be double the depth; and if there is very little water, the breadth and the depth should be equal. The depth of the water here alluded to is its natural depth, or that which it would have, if it did not meet the float-boards. The effective depth is generally two and a half times the natural depth, and is occasioned by the impulse of the water on the float-boards, which forces it to swell, and increases its action upon the wheel.

As it is of great consequence that none of the water should escape, either below the float-boards or at their sides, without contributing to turn the wheel, the breadth of the float-boards should be wider than the sheet of water which strikes them. The diameter of the water-wheel should be as great as possible, unless some particular circumstances in the construction prevent it; but ought never to be less than seven times the natural depth of the stream or thickness of the sheet of water, where it meets the float-boards. The wheel will move irregularly, sometimes quick and sometimes slow, according to the position of the floats with respect to the stream; unless the number of float-boards is considerable, the wheel must have so many floats, that

two floats will at least be always in the circular sweep at the bottom of the wheel; but in order to remove any inequality of motion in the wheel, and prevent the water from escaping beneath the tips of the float-boards, it should have as many float-boards as possible, without loading it, or weakening the rim on which they are placed. The float-boards should not be perpendicular to the rim, or, in other words, a continuation of the radius, but should be inclined to the radius; the water will thus heap upon the float-boards, and act not only by its impulse, but also by its weight. When the velocity of the stream is eleven feet *per* second, or above this, the inclination should never be less than thirty degrees; or when this velocity is less, the inclination should diminish in proportion; so that when it is four feet, or under, the inclination should be nothing, that is, the float-boards should point to the centre of the wheel.

It is a strong practical objection to this manner of applying the water to the wheel, that when the water of the river sinks in dry weather from a deficiency of water, it would not run over the top of the fall, and the mill could not work at all even if it sunk only ten or twelve inches: in like manner, when the water rises in floods, the water at the top of the fall would become so deep, as to require some shuttle to prevent it from inundating the wheels, at the same time that the stagnant water in the mill race would prevent the wheel from working. Almost all rivers are subject to floods, and often they rise and fall, three, four, six, and eight feet above their ordinary level in fair weather; now the water mostly rises at the tail or discharge of the water as much as the head, and the wheel-race will therefore be full of stagnant water, which is called tail-water, and obstructs the motion of the wheel.

In a ground-shot wheel, where the water issues from a shuttle on a level with the bottom of the wheel-race, it can always work in dry seasons, as long as the river contains any water, although the power diminishes almost to nothing, when the water sinks low, and will not rush out with force from the shuttle. In floods of water, this wheel has a greater advantage, because the depth of head which urges the flowing water is increased when the water is high, and this makes it drive the tail-water forcibly out of the wheel-race, and enable the wheel to work, when a wheel with an inclined fall would infallibly be stopped.

Breast-wheels and overshot-wheels, properly constructed, have still greater advantages, in clearing themselves from tail-water, and this is a very important object.

Floating-Mill with undershot Wheels.—A large floating water-mill, to be worked by the tides or currents, was stationed some years ago in the river Thames, between London and Blackfriars bridge, by permission of the Board of Navigation. Such permission having been granted with the view of reducing, if possible, the price of flour in the metropolis, and contributing to a constant supply of that necessary article of subsistence. The simplicity of this invention renders a long description superfluous, as it consists in merely applying the force of two large undershot water-wheels on each side of a barge, or any other vessel calculated to contain the interior part of the machinery; the float-boards are disposed in a proper manner to be acted on by the tide or current, so as to give the wheels a rotatory motion, and by connecting them with proper machinery, to answer the purposes for which the mill is intended.

Any ship, brig, sloop, or other vessel, may be used for this purpose, provided it is of sufficient size to accommodate the works to be erected, yet in point of expence it will be better to employ such as are rendered unfit for sea-service.

When it is intended that the ship or mill should be stationary, it must be anchored, moored, or otherwise made fast, so as to swing with the tide when necessary; but the mill may be worked while the vessel in which it is erected is sailing, when wind and other circumstances permit.

The number and size of the water-wheels to be used may be varied, according to the size of the ship or vessel, or to the strength of the tide or current, and the power required; and the wheels may be constructed as in common undershot mills, or with folding-floats, for the more readily freeing them from the water: two wheels are to be placed vertically, on an horizontal axis, of such length, that, the axis being placed across the ship or vessel, one wheel may run on each side of it on the same axis.

A mill constructed in the manner above described may be moved by the strength of from two to six large water-wheels, or such other number as the ship or vessel will accommodate. These water-wheels may dip into the water from three to four, or more feet deep; they should be so connected together as to be easily engaged with and disengaged from each other, so that during the weak part of the tide they may all be made to act on one pair of mill-stones, if necessary; and as the strength of the tide increases, more stones or other machinery may be put in motion, so as at all times to do business in proportion thereto.

In a mill of this kind the water-wheels do not admit of having water-courses, or any equivalent contrivances, to conduct the water to the wheels, as in other undershot wheels; but the float-boards must be large enough to receive the power required from merely dipping into the current of the tide-water.

The vessel of the mill in the Thames is the hull of an old ship of two or three hundred tons burthen, which being moored in the river by chains, so that it can swing round when the tide changes, the wheels will always turn the same way round; one water-wheel is fixed on each side of the vessel, a long iron axis being common to both; the extreme ends of the axis are supported in a frame-work of timber, and another very strong frame of timber is fixed outside of the wheels at the level of the water, which floats in the water, and is only attached to the mill by chains; this is to protect the wheels from injury, by vessels which pass and repass. Each water-wheel is 18 feet diameter, and 14 feet broad; the float-boards are each 3 feet deep, and are about sixteen in number, affixed on the circumference of cart iron-wheels, or circles, which are 12 feet diameter, there are three of these circles for each wheel; hence we find each float-board exposes a surface of 42 square feet to the action of the current, and if we suppose each wheel to have two floats in action at the same time, the power of the mill will be derived from 168 square feet acted upon by the water, which seldom exceeds a velocity of four miles *per* hour, or 352 feet *per* minute.

The iron axis of the water-wheels is a hollow tube of nine inches diameter outside, and five inches within, made in four lengths of 12 feet each, properly joined together, and extending across the vessel from one wheel to the other. On the middle of this axis a large wheel of 11 feet diameter is fixed, and surrounded by a brake or gripe like that used in a wind-mill, the use of which is to stop the mill when it requires repairing. Near to this brake-wheel is a large bevelled cog-wheel 13 feet diameter, with 89 cogs, which gives motion to a bevelled pinion two feet eight inches diameter, with eighteen cogs fixed on the top of a vertical axis. On this axis is also a large horizontal spur-wheel 12 feet diameter, with 201 cogs, which gives motion to pinions of one foot diameter, and 17 cogs fixed on the spindles of the mill-

stones. There are four pair of mill-stones, two pair of 4½ feet and two pair of 3½ feet diameter, and the mill also works a dressing-machine for the flour. The mill-stones make 57½ revolutions for one revolution of the water-wheels, which move very slow, scarcely two turns *per* minute, in the most favourable periods of the tide. The circumference of each taken through the middle of the float-boards is 47 feet; hence the float-boards move about 94 feet *per* minute, when the mill-stones make their proper number of revolutions to grind with the greatest effect.

It was found that on a flood-tide, this mill would drive two pair of 3½ feet mill-stones, and a flour dressing-machine, but on the ebb-tide only one pair of 4-foot stones and the machine; thus it is only the performance of a small mill, although the wheels are of large dimensions, and it would require enormous wheels to make an effective floating mill in the river Thames.

This machine is now removed from the river, because it was found to do so much injury to the vessels which continually ran against its floating frame, and the repairs of the damages frequently done to the mill by ice and the craft took away all the advantages of the mill.

Undershot Wheels with oblique Floats.—Attempts have been made to construct water-wheels for tide-rivers which receive the impulse obliquely, like the sails of a common wind-mill. This would in many situations be a great advantage. A very slow but deep river could in this manner be made to drive mills; and although much power would be lost by the obliquity of the impulse, the remainder might be very great. Dr. Robinfon speaks of a wheel of this kind which was very powerful; it was a long cylindrical frame, having a plate standing out from it about a foot broad, and surrounding it with a very oblique spiral like a cork-screw. This was immerfed about one-fourth of its diameter (which was nearly 12 feet), having its axis in the direction of the stream. By the work which it was performing, it seemed more powerful than a common wheel which occupied the same breadth of the river. Its length was not less than 20 feet; had it been twice as much it would have been nearly redoubled in its power without occupying more of the water-way. It is probable such a spiral continued quite to the axis, and moving in a hollow canal wholly filled by the stream, might be a very advantageous way of employing a deep and slow current.

In the Transactions of the Society of Arts, vol. xix. a water-wheel is described, in which the float-boards are placed obliquely to the axis of the water-wheel at about an angle of 40 degrees, being fixed to the rim in pairs, which are inclined equally to the axis of the wheel, but in opposite directions to each other; so that the two float-boards of each pair point towards each other in an angle of about 80 degrees, and if the pair of floats were continued they would meet in the middle of the breadth of the wheel. The water is made to strike the floats within this angle, and in consequence all the water which is emitted by the sluice and strikes upon the oblique floats will be reflected from the sides or ends of the two pair of float-boards towards the vertex of the angle, which they make; but the pair of floats do not touch each other, so that the vertex of the angle is open; but to prevent the water passing freely through the open angle, one of the float-boards is made to extend far beyond the vertex, or point, where they would intersect, and the other is made to fall short of it, nevertheless the water would certainly pass through the opening. It is stated, that the motion of the ordinary wheel with parallel floats is greatly retarded by the resistance which they experience in rising up or quitting the tail-water of the stream, from the pressure

pressure of the atmosphere on their upper surface before the air gets admission beneath the floats; but in Befant's wheel this resistance is greatly diminished, as the floats emerge from the stream in an oblique direction. The water-wheel is constructed in the form of a hollow drum, so as to resist the admission of the water. Although this wheel is much heavier than those of the common construction, yet it revolves more easily upon its axis, as the stream has a tendency to make it float. We cannot recommend this wheel, but on the contrary think it one of the worst forms, as it tends to increase that loss which arises in all undershot-wheels from the change of figure which the water must undergo when it strikes the float, and we should not have mentioned it, but that it has been so frequently copied and recommended by different authors.

Horizontal Water-wheels actuated by the Impulse of Water.

—These have been considerably in use on the continent, and deserve our notice from the simplicity of their construction. The wheel is constructed in the same manner as an undershot-wheel, having float-boards fixed round its circumference in the form of radii; it is mounted on a vertical axis, the upper end of which is fixed to the spindle of the mill-stone, if the mill is intended to grind corn; but in some cases, it is better to fix a cog-wheel on the upper part of the vertical axis with teeth round its edge, to give motion to trundles or pinions on the spindles of the mill-stones, because the floats of the wheel must always be made to move with a given proportion of the velocity of the water. The wheel-race or water-course may be made nearly the same as for an undershot-wheel, if we suppose it laid down in an horizontal position; that is, a trough or channel of masonry is constructed in which the wheel works, and the float-boards of the wheel are exactly fitted to it: at one end of this channel is the aperture or sluice through which the stream of water issues, and strikes the floats of the wheel so as to turn it round, and the water passes forwards and escapes at the other end of the channel. When the water is delivered upon the wheel in an horizontal direction, or perpendicular to its axis, the float-boards should be inclined about twenty-five degrees to the plane of the wheel, and the same number of degrees to the radius, so that the lowest and outermost sides of the float-boards may be farthest up the stream and be met by the water first.

In many cases, the water-course is made inclined to the plane of the wheel in such a degree, that the water may strike the float-boards perpendicular to their surfaces.

In the southern provinces of France, where horizontal water-wheels are generally employed, the float-boards are made of a curvilinear form so as to be concave towards the stream; they are generally segments of spheres, or hollow wooden bowls or ladles fixed on the rim of the wheel: the water, in this case, is conducted through a pipe, and projected in a jet on a direction a little inclined to the horizon. When the height of water is very considerable, this is, perhaps, the best form for the floats, or ladles, as they are called.

The chevalier de Borda observes, that in theory a double effect is produced when the float-boards are concave, but that the effect is diminished in practice, from the difficulty of making the fluid enter, and leave the curve in a proper direction. Notwithstanding this difficulty, however, and other defects which might be pointed out, horizontal wheels with concave float-boards are always superior to those in which the float-boards have plane surfaces.

Mr. Smeaton constructed a small corn-mill with a horizontal water-wheel, of which the following are the principal dimensions. Fall of water $52\frac{1}{2}$ feet; diameter, or

bore of the nose-pipe through which the water issued in a jet to strike upon the wheel, $1\frac{1}{2}$ inch; diameter of the water-wheel 10 feet to the centre of the floats or ladles, which were twelve in number; they were made of a concave form, nearly segments of spheres, and about 14 inches in diameter; and fixed round the circumference of the wheel, so that the planes of the circular rims, or edges of the hollow ladles, were not perpendicular to the plane of the wheel, but inclined thereto in such a degree, that the jet of water issuing from the nose-pipe at an angle of 22 degrees from the horizontal line, would strike the floats in the centre and perpendicular to the circular edge of the hollow; the internal surface of the floats being really spherical, the water would always strike perpendicularly into the concavity of the bowl. The water-wheel axis rose up perpendicularly into the mill-house, and on the top a wheel of 4 feet 8 inches in diameter, and 44 cogs, was fixed for giving motion to the pinions on the axis of the mill-stones. The largest pinion of 17 cogs was fixed on the axis of a pair of stones 4 feet 6 inches in diameter, and the smaller pinion of 13 cogs on the axis of a stone 3 feet 6 inches in diameter. It was not intended to turn both these pairs of stones at the same time, but it was necessary to have two pairs for different uses.

When this mill moved with a proper velocity to grind to the greatest advantage, if the 4 feet 6 inches stones were used, the water-wheel made 25 revolutions *per* minute, and the stones therefore made 65 revolutions *per* minute, and the float-boards moved with a velocity of 784 feet *per* minute; but when turning the smaller mill-stones of 3 feet 6 inches diameter, the water-wheel went best when it made 26 revolutions, and therefore turned the mill-stone 88 turns *per* minute; and the velocity of the floats was 816 feet *per* minute.

Mr. Smeaton calculated the velocity of the water issuing from the pipe at 3403 feet *per* minute, which is the velocity due to a 50 feet fall, because he allowed the $2\frac{1}{2}$ feet to overcome friction, and the expenditure of the $1\frac{1}{2}$ inch nose-pipe at 30 cubic feet *per* minute allowing for friction. This mill ground one bushel of wheat *per* hour, on the average of a great many experiments, now $30 \times 50 = 1500$ cubic feet, falling one foot *per* minute. It is found by repeated experiments, that 600 cubic feet falling one foot *per* minute on a good water-wheel is an ample allowance for grinding a bushel of wheat, as it may be done by 530; hence this fall of water ought to have ground $2\frac{1}{2}$ bushels *per* hour instead of one. The mill, however, admits of improvement in making the floats of the wheel move quicker.

When the mill-stone of an horizontal mill is fixed on the upper end of the axis of the water-wheel, if the mill-stone be five feet in diameter, it should never make less than sixty turns in a minute, and the wheel must perform the same number of revolutions in the same time; and in order that the effect may be a maximum, or the greatest possible, the velocity of the current must be more than double that of the wheel.

Suppose the mill-stone, for example, to be 5 feet diameter, and the water-wheel 7 feet, it is evident that the mill-stone and wheel must at least revolve 60 times in a minute; and since the circumference of the wheel is 22 feet, the float-boards will move through that space in the 60th part of a minute, that is, at the rate of 22 feet *per* second; which being doubled, makes the velocity of the water 44 feet one second, answering, as appears from the rule, for the velocity of falling water, to a fall of 30 feet. But if the given fall of water be less than 30 feet, we may procure the same velocity to the mill-stone, by diminishing

ing the diameter of the wheel. If the wheel, for instance, is only 6 feet diameter, its circumference will be 18.8 feet, and its floats will move at the rate of 18.8 feet in a second, the double of which is 37.6 feet *per* second, which answers to a head of water 22 feet high. The diameter of the water-wheel, however, should never be less than 6 or 7 feet, because the float-boards change their direction so rapidly, in consequence of their proximity to the centre, that they will not receive the full action of the water, because it acts in a perpendicular direction to the float-board only for a moment. Hence there will be a certain height of the fall, beneath which the simple horizontal wheel cannot be employed; and beyond that, wheel-work must be introduced to obtain the requisite velocity for the mill-stones.

In the provinces of Guienne and Languedoc, in France, another species of horizontal wheel is employed for turning machinery. It consists of an inverted cone, with spiral float-boards of a curvilinear form winding round its surface. The wheel moves on a vertical axis in a pit or well of masonry, to which it is exactly fitted, like a coffee-mill in its box. It is driven chiefly by the impulse of the water, conveyed by a spout or canal in a stream, which strikes the oblique float-boards; and when the water has spent its impulsive force, it descends along the spiral float-boards, and continues to act by its weight till it reaches the bottom, where it is carried off by a canal. The idea of this machine is ingenious. The jet of water, being first applied to the upper or largest part of the cone, strikes the float-boards at the part where they move with the greatest velocity, in consequence of their being on the largest radius; but as the water loses its velocity, in consequence of the motion it has imparted to the wheel, it descends in the cone, and acts upon the floats lower down, where, the radius being less, the floats move more slowly, and are therefore better adapted to receive the action of the water with its diminished velocity.

M. Mannoury Desfont's horizontal Water-Wheel, which he calls Danaide.—This receives the impulse of the water in a different manner from any which we have described, and is described in a report to the Institute of France in 1813. The water-wheel is fixed in a horizontal position upon a vertical axis, and supported upon the pivots thereof, so as to be capable of turning round. It is not in reality a wheel, but a hollow cylinder or drum capable of containing water; it is open at top, and united to the axis in the centre of the circular plane, which forms the bottom. Within this drum, and concentric with it, a solid cylinder is fixed; it is of less dimensions than the drum itself, and occupies such portion of the content of the drum as to reduce the open part which can contain water to a hollow ring or circular trough, open at top, and of a considerable depth, but only a few inches in width. The depth is described as being nearly as great as the diameter of the wheel.

The water coming from an elevated reservoir, is projected in jets from one or more pipes into this annular space which surrounds the rim of the wheel. These pipes descend in an inclined direction, till they are nearly on a level with the surface of the water in the annular space; and the extremities turn horizontally, so as to project the jet horizontally, and in the direction of tangents to the mean circumference of the water contained in the annular space.

Suppose this space which surrounds the wheel is full of water, then the stream issuing from the jet causes the wheel to turn round upon its axis, because it takes hold or acts upon the water in the annular space, and tends to give the water a circulating motion within the annular space; but the

friction, or resistance, which the water would find in such circulation, causes the wheel to turn round with the water, unless the load on the wheel, or resistance to its motion, is too great.

The water which is continually thrown into the wheel escapes from the annular space by passages which proceed from the bottom thereof to the centre of the wheel; and there are openings at the centre, where the water can drop out *below*. To form the passages for this purpose, the solid cylinder which is fixed in the centre of the hollow drum is of less depth than the other, and leaves a space between the bottom of the solid and the bottom of the hollow, which is divided into compartments by diaphragms fixed upon the bottom of the trough, and proceeding like radii from the circumference to a central hole in the bottom of the trough, which is left open to allow the water to escape. The report states, that the velocity with which the water issues from the jets makes the machine move round its axis; and this motion accelerates by degrees, till the velocity of the water in the annular space equals that of the water from the reservoir, so that no sensible shock is perceived of the affluent water upon that which is contained in the machine. The motion of the wheel is regular, because the action is continual; but in the case of other water-wheels, where the water strikes against float-boards, such boards must necessarily be of a determinate number, and the motion must be given to the wheel by a succession of impulses, as the floats arrive before the stream. We might indeed suppose a wheel with an infinite number of floats, but it would then amount to a plain cylindrical or flat surface, upon which the water would not take sufficient hold to produce any sensible effort to turn it round.

Now in M. Desfont's wheel, in place of float-boards, the rim of the wheel is clothed with water, which is capable of being acted upon by the water issuing from the jets. This action tends to put the water in the annular space in motion, and to carry the wheel along with it, by the adhesion it must naturally have to the sides of the channel which contains it. The velocity of the wheel will be in proportion to the resistance that the load makes to its motion.

The circular motion of the wheel communicates a centrifugal force to the water contained in the annular cavity of its rim, which causes it to press against the outermost side of the channel. This centrifugal force acts equally upon the water contained in the compartments at the bottom of the said rim; but its action diminishes as the water approaches the centre.

The whole mass of water is then animated by two opposite forces, *viz.* gravity and the centrifugal force. The first tends to make the water run out at the hole in the bottom of the wheel at the centre, and the second to drive the water from that hole.

To these two actions are joined a third, *viz.* friction or resistance, which acts an important and singular part; and in this machine the friction of the water produces its powers of action, while in most other machines it always diminishes their powers. The effect in this machine would be nothing, were it not for the resistance which the water finds opposed to its free circulation in the annular space round the rim of the wheel.

By the combination of these three forces there ought to result a more or less rapid flow of water from the hole in the centre at the bottom of the wheel; and the slower this water issues, the greater will be the effective power of the machine for producing the useful effect for which it is destined.

The moving power in this machine, like all others, is the weight of the water which runs into the wheel, multiplied by

by the elevation the reservoir has above the bottom of the wheel, or orifice from which it issues in quitting the same; but the useful mechanical effect is stated to be equal to that product, diminished by half the force which the water retains, when it flows out at the orifice below, and quits the machine.

In order to ascertain, by direct experiment, the magnitude of this effect, Messrs. Prony and Carnot fixed a cord to the axis of the machine, which passing over a pulley, raised a weight by the motion of the machine. By this means the effect was found to be $\frac{7}{10}$ ths of the power, and often approached $\frac{7}{10}$ ths, without reckoning the friction of the pulleys, which has nothing to do with the effect.

We cannot help suspecting some mistake in these experiments, or in the statement of them, but think the machine deserves a trial; and if it should produce near the result above stated, it would be a most valuable addition to our means of employing falls of water; and its simplicity would be a great recommendation, particularly for corn-mills, because the perpendicular axis is immediately adapted for that purpose, without any wheel-work.

Horizontal Mill with oblique Vanes.—In Belidor's Architecture Hydraulique he describes a different form of horizontal mill. The wheel is a circular rim, and the radii or arms are all oblique vanes or floats, precisely the same as the common smoke-jack. This wheel is placed horizontally in a well, to which it is exactly fitted, but the rim of the wheel does not touch the circular wall of the well. The axis of the wheel ascends upwards into the mill-house, and the spindle of the mill-stone is fixed into it. A horizontal arch-way is conducted to the well sideways, and above the part where the wheel is situated. This arch conveys the water into the well over the wheel; and beneath the wheel there is a similar horizontal arch to carry away the water, after it has passed through the wheel, that is, in the spaces between its vanes or floats. The weight of the water presses upon them in a perpendicular direction, and the planes of these floats being all inclined to the horizon, the action of the pressure tends to turn the wheel round on its axis, by the same action as the smoke upon the vanes of a jack, or like a wind-mill.

The water is supplied in such a body through the upper arch, that the well is always kept full, with a considerable depth of water pressing upon the wheel; whilst the lower arch carries away the water so freely, that it runs away from beneath the wheel as fast as it can pass through the vanes of the same.

The mill described by Belidor was at Toulouse, and contained a number of such wheels in a row, each giving motion to one pair of stones.

Horizontal Machines moved by the Reaction of Water.—The reaction of water, issuing horizontally through a spout or orifice, may be employed to communicate motion to machinery; and though this principle has not yet been adopted in practice, it appears from theory, and from some detached experiments on a small scale, that a given quantity of water, falling through a given height, will produce greater effects by its reaction than by its impulse. If we suppose a vertical pipe of any given height, open at both ends, and that water is poured into it at the top, the water will issue at the bottom of the pipe with a velocity proportioned in a certain manner to its altitude, because every particle of water which issues is pressed upon and impelled by the weight of all the particles which are above it. Now, suppose the pipe bent or curved at the bottom, so that it will turn the stream of water into a horizontal position; in this case, the pressure and force, of which we have spoken, will be deflected from the vertical direction to the horizontal. Now

it is clear that the bent part of the pipe, or some part of the interior surface of the tube opposite to the orifice, must sustain all the pressure which is thus deflected or transmitted in another direction; and if the tube is freely suspended, it will retreat before this pressure, and be put in motion. If we suppose the tube to have no resistance to motion, then it would receive all the motion of the water, which would not move at all after it issued from the orifice, but the orifice and tube would move away from the water. This is an impossible case, and in reality the motion of the effluent water will be divided between the pipe or tube and the issuing water, in proportion to the resistance with which each is loaded. Another and perhaps more familiar explanation is, that the water presses against every part of the interior part of the pipe, except against the orifice or aperture, which is open; and in consequence, the unbalanced pressure on the part opposite to the orifice will tend to put the pipe in motion. A sky-rocket mounts in the air from a similar cause.

Dr. Barker's mill by the reaction of water was the first of this kind of machines, and is described by Desaguliers, in 1743. In his Experimental Philosophy, vol. ii. p. 460, he calls it a machine to prove Mr. Parent's proposition experimentally, viz. that an under-shot water-mill does most work, when the water-wheel moves with only a third part of the natural velocity of the water that drives it. He says, that Dr. Barker had this thought, and communicated it to him, saying, that it would be an experimental proof of Mr. Parent's proposition; in consequence of which, Desaguliers made a working model of it, which he shewed to the Royal Society, and the experiments upon it, at their meeting in 1742.

It consists of an upright pipe or trunk, communicating with two horizontal branches, like an inverted T; thus, \perp . This perpendicular pipe is poised upon a pivot at the lower end, and the upper end is connected with the spindle of the mill-stone, or other machine to which it is to communicate motion. The top of the pipe is formed into a funnel, into which a stream of water is conducted, and runs down the pipe: the water escapes through a hole in each of the horizontal arms, which holes are near the ends of the arms, and open in opposite directions, and in such a position that they will direct the stream of water horizontally, and nearly at right angles to the length of the arms.

Suppose water to be poured in at the top of the tube from the spout, it will then run out by the holes at the ends of the arms, with a velocity corresponding with the depth of these holes beneath the surface of the water in the vertical pipe. The consequence of this must be, that the arms must be pressed backwards, for there is no solid surface at the hole on which the lateral pressure of the water can be exerted, while it acts with its full force on the inside of the tube opposite to the hole. This unbalanced pressure, acting upon the opposite sides of both arms, will make the tube and the horizontal arm revolve upon the spindle as an axis.

This will be more easily understood, if we suppose the orifices to be shut up, and consider the pressure upon a circular inch of the arm opposite to the orifice, the orifice being of the same size.

The pressure upon this circular inch will be equal to a cylinder of water, whose base is one inch in diameter, and whose altitude is the height of the fall; and the same force is exerted upon the shut-up orifice. These two pressures being equal, and acting in opposite directions, the arm will remain at rest; but as soon as the orifice is opened, the water will issue with a velocity due to the height of the fall. The pressure of the water upon the orifice will now be removed, and as the pressure upon the circular inch opposite

from the lower end of the column will acquire the same velocity of motion, from the uniform pressure of the thirty cubic inches which are above it, that one cubic inch let fall from the top would acquire in falling down to the level of the aperture, *viz.* such a velocity as in a contrary direction would throw or project it to the level from whence it fell, the weights and velocities in both these cases being equal, the products, or what we have called mechanical powers, will also be equal. We might therefore be led to suppose, that a cubic inch of water, let fall through a space of thirty inches, so as to impinge upon a solid body, would be capable of communicating thereto an equal motion or mechanical effect by collision, as if the same cubic inch had descended through the same space with a slower motion, and produced the effect gradually; for in both cases gravity acts upon an equal quantity of matter through an equal space.

It is true that the gravitating force acts a longer space of time upon the body that descends slowly, than upon the other which falls quickly; but this cannot occasion the difference in the effect: for we find by experiment, that an elastic body falling through any given space will, by collision upon another elastic body which is fixed, rebound nearly to the height from which it fell: or, by communicating its motion to a body equal to itself, will cause that body to ascend to the same height. On these principles we might conclude, as some authors have done, that whatever was the ratio between the power and effect in undershot wheels, the same would hold true in overshot, and indeed in all others.

However conclusive this reasoning may seem, it will appear, in the course of the following deductions, that the effect of the gravity of descending bodies is very different from the effect of the stroke, of such as are *non-elastic*, though generated by an equal mechanical power.

It is true that, in the cases we have above supposed, the power of the fall of water is the same; but the problem proposed to the engineer is, to obtain from it all or as much as possible of the power, and render it applicable to some useful purpose. We have already given our definition of *power*, that it is weight or matter compounded with motion. Now to obtain all the power from any stream of water, we must abstract from it all its weight and all its motion. In undershot wheels, or any others moved by the impulse of the water, we cannot come near this, because we have already shewn, that the greatest effect is produced, when the velocity of the wheel is two-fifths of the velocity of the moving water. The water, after it has finished its effect, is discharged with that velocity; hence it retains and carries away with it three-fifths of its original power. Neither can we obtain the full effect of the weight of the water, for another loss is sustained, in the change of figure which the water experiences, when it strikes the float-board. This is much greater than is usually supposed, in considering machines, although it must be familiar to any one who considers the resistance of a boat, or other body, when drawn through water. No weight is raised in these cases, unless the motion be rapid, (so as to raise a wave before the moving body;) but all the power is expended in changing the figure of the water, by dividing the particles, and putting them in new positions, so that the body can pass between them.

It is to this source that we must look, for the difference between two-fifths of the power, which we find is abstracted from the whole power of the water by an undershot-wheel, and one-third of the power, which is the utmost we can obtain by means of an undershot wheel.

In the other class of machines, which are actuated by the weight of water, we can obtain a much greater share of the power of the descending water. The weight of the water

is borne by the machine, which must therefore receive the whole weight of the water, and the loss is chiefly in the motion which the water still retains after departing from or quitting the machine; but as we are not confined, as in the former instance, to any fixed velocity of motion for the wheel, we may make it move almost as slowly as we please, so that the water will carry away with it a very small share of the velocity which it would have acquired by falling through the height of the fall. Indeed, if we could suppose a wheel to be without friction, and no water to leak or escape from those vessels, or parts of the wheel which contain the water, it would be possible to obtain an effect from it very nearly equal to the power.

Breast-Wheels.—These are very commonly called undershot wheels, because the water runs beneath the wheel, but improperly, because the water does not shoot against the floats of the wheel, or at least the principal power is derived from the weight of the water. A breast-wheel partakes of the nature of both an overshot and an undershot, and is constructed as is represented in *fig. 1. Plate I. of Water-wheels.* The lower part of the wheel is surrounded by a curved wall or sweep of masonry, which is made concentric with the wheel, and the float-boards of the wheel are exactly adapted to the masonry, so as to pass as near as possible thereto without touching it; and the side walls are in like manner adapted to the end of the float-board or sides of the wheel, the intention being, that as little water as possible shall be able to pass by the float-boards without causing the boards to move before it. The water is poured upon the wheel over the top of the breast at I, the efflux from the mill-dam R being regulated by the sluice or shuttle M, which is placed in the direction of a tangent to the wheel, and is provided with a rack N, and pinion P, by which it can be drawn up so as to make any required degree of opening, and admit more or less water to flow on the wheel.

The water first strikes on the float, and urges it by its impulse; but when the floats descend into the sweep, they form as it were close buckets, each of which will contain a given quantity of water, and the water cannot escape from these buckets except the wheel moves, at least this is the intention, and the wheel is fitted as close as it can be to the race with that view. Each of the portions of water contained in these spaces bears partly upon the wall of the sweep, and partly upon the floats of the wheel; and its pressure upon the floats, if not exceeded by the resistance, will cause the wheel to move; hence the action upon all the floats which are within the sweep of the breast is by the weight of the water alone; but the water is made to impinge upon the first float-board with some velocity, because the surface of the water in the dam K is raised considerably above the orifice beneath the shuttle where the water issues.

The upper part of the fall at I is rounded off to a segment of a circle called the crown of the fall, and the water runs over it. The lower edge of the shuttle when put down is made to fit to this curve, so as to make a tight joint; and in consequence when the shuttle is drawn up, the water will run between its lower edge and the crown in a sheet or stream which strikes upon the first float that presents itself, nearly in a direction perpendicular to the plane of the float-board, or of a tangent to the wheel. The float-boards of the wheel are directed to the centre, but there are other boards placed obliquely which extend from one float-board to the rim of the wheel, and nearly fill the space between one float-board and the next. These are called rising-boards, and the use of them is to prevent the water flowing over the float-board into the interior of the wheel; but the edges of these

these boards are not continued so far as to join to the back of the next float, because that would make all the boards of the wheel close, and prevent the free escape of the air when the water entered into the spaces between the floats.

As the water strikes with some force, the rising-board is very necessary, to prevent the water from dashing over the float-boards into the interior of the wheel.

This is the form of breast-wheel employed by Mr. Smeaton in the great number of mills which he constructed; but although he speaks of the impulse of the water striking the wheel, he always endeavoured to make the top of the breasting or crown of the fall as high as possible, so as to attain the greatest fall and the least of the impulsive action. All rivers and streams of water are subject to variation in height from floods or dry seasons, and in some this is very considerable; it was therefore necessary to make the crown I of the fall at such a height as that in the lowest state of the water R, it would run over the crown in a sheet of three or four inches in thickness, and work the wheel. When the water rose higher in the mill-dam, it would then have a pressure to force it through, and in that case would strike the wheel so as to impel it by the velocity.

Mr. Smeaton was well aware that the power communicated by this impulse was very small. In some cases, where the water was very subject to variation, he used a false or moveable crown, that is, a piece of wood which fitted to the crown I, and raised the surface thereof a foot or more, so as to obtain the greatest fall when the water stood at a mean height; but when the water sunk too low to run over this moveable crown, it could be drawn up to admit the water beneath it. This effect has since been produced in a more perfect manner by making the crown of the fall a moveable shuttle, to rise and fall according to the height of the water in the mill-dam, by which means the inconvenience before-mentioned is avoided.

Improved Breast-wheel, in which the Water runs over the Shuttle.—Fig. 7. is a section of one of this kind. A is the water which is made to flow upon the float-board B, and urges the wheel by its weight only, the water being prevented from escaping or flowing off the float-boards by the breast or sweep D D, and the side-walls which inclose the floats of the wheel. The upper part of the breast D D is made by a cast-iron plate, curved to the proper sweep to line with the stone-work. On the back of the cast-iron plate the moving shuttle *e* is applied; it fits close to the cast-iron so as to prevent the water from leaking between them, and the water runs over its upper edge. F is an iron groove or channel let into the masonry of the side-walls, and in these, the ends of the sliding shuttle are received; *f* is an iron rack, which is applied at the back of the shuttle, and ascends above the water-line where the pinion *g* is applied to it to raise or lower the shuttle. The axis of the pinion is supported in a frame of wood I I; *b* H is a toothed sector and balance-weight, which bears the shuttle upwards, or it might otherwise fall down by its own weight, and put the mill in motion when not intended. G is a strong planking, which is fixed across between the two side-walls, and retains the water when it rises very high, as in time of floods; but in common times the water rises only a few inches above the lower edge of the planking. When the shuttle is drawn up to touch this lower edge, the water cannot escape; but when the shuttle is lowered down, it opens a space *e* through which the water flows upon the float-boards of the wheel. This was the form first adapted for the falling-shuttle, but its construction has since been much improved.

Fig. 4. Plate II. is a section of the most improved form for a breast-wheel, taken from the Royal Armoury Mills, at

Enfield Lock, erected by Messrs. Lloyd and Ostel. The general description of this, is like the former, but it is constructed in a better manner, and unites strength with durability. The breast of masonry is surmounted by a cast-iron plate A $2\frac{1}{2}$ feet high, which is let into the masonry of the side walls at each end, and the lower part is formed with a flanch, by which it is bolted to the stone-breast at top. This plate is made straight at the back for the shuttle B to lie against, and it slides up and down. The ends of the gate are guided by iron groove pieces or channels which are let into the stone-work of the side walls, and being made wedge-like, they fix the ends of the cast-iron breast fast in its place. The grooves are not upright, but inclined to the perpendicular so much, that the plane of the gate is at right angles to a radius of the wheel drawn through the point where the water falls upon the wheel. D is a strong plank of wood, extended between the iron grooves just over the shuttle. When the shuttle is drawn up it comes in contact with the lower side of this piece of wood, and stops the water; but the piece D is fixed at such a height, that the water will run clear beneath it, unless its surface rises above its mean height.

The float-boards of the wheel do not point to the centre of the wheel, but are so much inclined thereto that they are exactly horizontal at the point where the water first flows upon them. In this way, the gravity of the water has its full effect upon the wheel, and the boards rise up out of the tail-water in a much better position, than if they pointed to the centre of the wheel; and this is more particularly observable when the wheel is flooded by tail-water penned up in the lower part of the race, so that it cannot run freely away from the wheel. The dimensions of this wheel are as follow:—Diameter 18 feet to the points of the floats, and 14 feet wide; the float-boards are 40 in number, each 16 inches wide, and each rising-board 11 inches wide. The wheel is formed of four cast-iron circles or wheels, each 14 feet 8 inches diameter, placed at equal distances upon the central axis, which is 14 feet 8 inches long between the necks or bearings, and 9 inches square; the bearing-necks are $9\frac{1}{2}$ inches diameter. The wheel is calculated to make four revolutions *per* minute, which gives near $3\frac{1}{2}$ feet *per* second for the velocity with which the float-boards move. The fall of water is six feet, and the power of the wheel, when the shuttle is drawn down one foot perpendicular, equal to 28-horse power.

Breast-Wheel with two Shuttles.—In this wheel the piece of wood marked D in the last figure, is fitted into the groove of the shuttle, and is provided with racks and pinions to slide up and down, independently of the lower shuttle. The intention of this is, to make the lower shuttle rise and fall, according to the height of the water, so that the water shall always run over the top of it, in the proper quantity to work the mill with its required velocity, whilst the upper shuttle is only used to stop the mill by shutting it down upon the lower shuttle, and preventing the water from running over it. This plan is used when the mill is to be regulated by a governor, or machine to govern its velocity; in that case the governor is made to operate upon the lower shuttle, and will raise it up, or lower it down, according as the mill takes too much or too little water, and this regulates the supply; but the upper shuttle is used to stop the mill, and by this means the adjustment of the lower shuttle is not destroyed, but when set to work again, it will move with its required velocity. Fig. 3. Plate II., *Water-wheels*, is a section of one of the water-wheels at the cotton-mills of Messrs. Strutt, at Belper, in Derbyshire. The width of this wheel is very great, and to render the shuttles A B firm, a strong

grating of cast-iron, is fixed on the top of the breast K, and the shuttles are applied at the back of the grating E, so as to slide up and down against it, the strain occasioned by the pressure of the water being borne by the grating. The lower shuttle is moved by means of long screws, *a*, which have bevelled wheels, *b*, at the upper ends, to turn them, by a connection of wheel-work with the wheel-work of the mill. The upper shuttle, A, is drawn up or down by racks and pinions, *c*, which are turned by a winch, or handle. The bars of the grating E are placed one above the other, like shelves, but are not horizontal; they are inclined, so that the upper surfaces of all the bars form tangents to an imaginary circle of one-third the diameter of the wheel described round the centre thereof. These bars are not above half an inch thick, and the spaces between them are $2\frac{1}{2}$ inches. The bars are of a considerable breadth, the object of them being to lead the water, with a proper slope, from the top of the lower shuttle A to flow upon the floats of the wheel. This disposition allows the shuttles to be placed at such a distance from the wheel as to admit very strong upright bars of cast iron to be placed between the wheel and the shuttles, for the shuttles to bear against, and prevent them from bending towards the wheel, as the great weight of water would otherwise occasion them to do. These upright bars are very firmly fixed to the stone-work of the breast at their lower ends, and the upper ends are fastened to a large timber, D, which is supported at its ends in the side walls, and has a truss-framing applied to the back of it, like the framing of a roof, to prevent it from bending towards the wheel. The upright bars are placed at distances of five feet asunder, so as to support the shuttles in two places in the middle of their length, as well as at both ends; and large rollers are applied in the shuttle, where it bears against these bars, to diminish the friction, which would otherwise be very great.

These precautions will not appear unnecessary when the size of the work is known. The wheel is $21\frac{1}{2}$ feet in diameter, and 15 feet broad; the fall of water is 14 feet, when it is at a mean height; the upper shuttle is $2\frac{1}{2}$ feet high, and 15 feet long; the lower shuttle is 5 feet high, and the same length, so that it contains 75 square feet of surface exposed to the pressure of the water: now taking the centre of pressure at two-thirds of the depth, or $3\frac{1}{3}$ feet, we find the pressure equal to that depth of water acting on the whole surface; that is, the weight of $3\frac{1}{3}$ cubic feet of water = 208 lbs. bears on every square foot of surface, which is equal to 15,600 lbs., or near 7 tons on the lower shuttle only; but if we take the two shuttles together, the surface is 112 square feet, and the mean pressure 312 lbs. upon each, or 16 tons in the whole. The wheel has forty float-boards pointing to the centre. The wheel is made of cast-iron. There are two wheels of the dimensions above stated, which are placed in a line with each other, and are only separated by a wall which supports the bearings; for they work together as one wheel, and the separation is only to obviate the difficulty of making one wheel of such great breadth as 30 feet, though this is not impossible, for there is a wheel in the same works 40 feet in breadth, but it is of wood and not in iron, framed in a particular manner, as we shall soon describe.

Mr. Buchanan's Bucket Water-Wheel for a low Fall.—We have already shewn, that where water can be made to act on a wheel by weight, it is much more effectual than when the same water is made to act by impulse; and we shall shew this more fully in speaking of overshot-wheels.

Where the fall is less than half the diameter of the wheel, if the buckets are made in the usual form of the buckets for overshot-wheels, the difficulty of filling them

with water, and the short time they are able to retain the water, are such great defects, that in such cases breast-wheels, with open float-boards, such as we have described, have been found in practice to be more advantageous than bucket-wheels.

Mr. Buchanan suggests, that, by adopting another form of the buckets, they might be made as to be easily filled, and at the same time capable of retaining the water in a situation to produce nearly its full effect altogether by weight, on a low fall.

In a wheel of this construction, contrary to the usual practice, the water must be poured into the buckets from within the circle of buckets instead of from without the circle of buckets. How the filling of the buckets from within can be accomplished may not at first be obvious; but it may be done without the pentrough, which supplies the water, making any interference with the arms of the wheel, if it is constructed as shewn in *figs. 4. and 5. Plate I. Water-wheels.* *Fig. 4.* is an horizontal section of the wheel, and plan of the pentrough; and *fig. 5.* an elevation of the water-wheel.

The buckets in the figure, empty themselves by means of apertures on the outside of the wheel, which are the whole length of the buckets, but no wider than just sufficient to discharge the water from the buckets when they arrive at the bottom of the wheel, and before they begin to ascend. A A is the pentrough, into which the supply of water is conducted. From B to C a part of the wheel is represented, with the shrouding removed, to shew the form of the buckets, and the situation of the water in them; *a, a, a,* are the apertures by which the water escapes from the buckets; *b* the aperture by which the water enters from the pentrough to the buckets. The plan, *fig. 4.*, shews, that the arms, N N, of the wheel, and the circular rims which support the buckets, occupy only a small part of the breadth of the circular ring of buckets M; so that about one-third of the length of the buckets at each end is exposed on the inside of the circle, and against these parts the penstock is applied, as shewn at A A, and the arms and rim of the wheel, move clear of it; but the buckets, as they pass, receive water, which flows in a continual stream at the orifices, *b, b,* of the pentrough; the buckets there become filled from the inside. The partition-boards or plates which form the buckets are represented by the white lines in *fig. 5.*, and are so shaped, that they will retain nearly the whole of the water until they arrive at the lowest *a*; the water then begins to escape, and by the time that each bucket arrives at the lowest point of the wheel, it will have discharged all the water, and will rise up empty.

This is a truly ingenious contrivance; but we fear that in the execution it would present many difficulties, particularly the ring of buckets M, which could not, we think, be so firmly affixed, supported by the narrow bearing of the two rings and arms N, as to preserve their circular figure for any great length of time; and any bending or warping of such a heavy mass as a water-wheel will soon destroy it. Neither is the advantage which could be derived from receiving the water in close buckets, instead of open float-boards, so great as is generally imagined.

On the Power and Effect of Breast-wheels.—We shall fully examine the different effects of the power of water, when acting by its impulse and by its weight, under the title of *overshot-wheels.* In breast-wheels of the common construction, the effects of impulse and weight are combined; but what is there described being carefully attended to, the application of the same principles in these combined cases will be easy.

All kinds of machines, where the water cannot descend through a given space, unless the wheel moves therewith, are to be considered as of the same nature with overshot-wheels, and equal in power and effect to an overshot-wheel, in which the perpendicular height that the water descends from is the same. All those machines that receive the impulse or shock of the water, whether in an horizontal, perpendicular, or oblique direction, are to be considered of the same nature as undershot-wheels. Therefore, in a wheel which the water strikes at a certain point below the surface of the water in the mill-dam, and after that descends in the arc of a circle, pressing by its gravity upon the floats of the wheel, the power will be equal to the effect of an undershot-wheel, whose fall is equal to the difference of level, between the surface of the reservoir and the point where it strikes the wheel, added to that of an overshot, whose height is equal to the difference of level between the point where it strikes the wheel and the level of the tail-water.

It is here supposed that the wheel receives the shock of the water at right angles to its radii, and that the velocity of its circumference is properly adapted to receive the utmost advantage of both these powers; otherwise a reduction must be made on that account.

Mr. Ostel, an experienced engineer, informs us, that the velocity of the water-wheel's circumference should always be between three and four feet *per second*; but he has not been able to determine which of these two velocities is the best, except in cases where a wheel is subject to be flooded by tail-water; and in that case four feet *per second* is best. Mr. Smeaton advised $3\frac{1}{2}$ feet.

On overshot Water-Wheels.—An overshot-wheel is simply a circular ring of open buckets, so disposed round the circumference of a vertical wheel, as to receive the water from a spout placed over the wheel in such a manner, that the buckets on one side of the wheel shall be always loaded with water, whilst the other side is empty: in consequence, the loaded side will cause it to descend; and by this motion the water runs out of the lower buckets, while the empty buckets of the rising side of the wheel, in their turn come under the spout, and are filled with water.

A machine so simple does not appear to present any difficulties in its execution, which should require any application of theoretic reasoning to remove them; but in reality it is a matter of some delicacy to construct a wheel in such a manner as to obtain the greatest effect from a given fall of water.

It is probable, that the earliest overshot water-wheels consisted of a number of wooden boxes or bowls, fastened on the circumference of the wheel; but these would soon give place to a better mode of construction, in which the circumference of the wheel being surrounded by a circular ring at each side, the space between them was divided into separate buckets by partition-boards. These partitions did not point to the centre of the wheel in the direction of radii, but were inclined thereto nearly in an angle of forty-five degrees. By this means, the water which issued from the spout of the trough above, nearly in an horizontal direction, as a tangent to the wheel, would run into the buckets, and fill them as they arrived in succession at the top or highest point of the wheel; but as the buckets changed their position by the descending-motion of one side of the wheel, they would become inclined, and the water contained in the buckets would begin to run over the edges of the partitions between the buckets, and by the time the bucket arrived at the bottom point of the wheel, the whole of the water would be run out and leave the bucket empty, and they would remain empty whilst they ascended on the opposite side of the wheel. By this

means, a constant preponderance of one side of the wheel would be kept up by the water falling into the buckets at the top of the wheel, and flowing from it at the bottom.

The points chiefly to be considered in constructing an overshot-wheel are, first, that the water shall be applied on the circumference of the wheel, so as to be incapable of descending without communicating motion to the wheel, until the water has descended to its lowest position, and that it shall then quit the wheel entirely; secondly, that the utmost height of fall shall be attained and usefully employed; and thirdly, that the load or resistance to the motion of the wheel shall be so adapted and proportioned to the weight of water which is applied in the descending-buckets of the wheels, that the wheel will move slowly; because we have before shewn, that whatever velocity the wheel moves with, so much velocity the water must retain when it quits the wheel, and will thus carry away some power with it.

We shall now proceed to consider all the particulars which contribute to the attainment of these objects, taking Mr. Smeaton for our guide, and only adding such observations as appear necessary to render his maxims more clear.

I. *On the maximum Effect which can be obtained from a Fall of Water by Means of an overshot-Wheel.*—The effective power of the fall of water must be reckoned upon the whole descent, because it must be raised that height, in order to be in a condition to produce the same effect a second time. The ratio between the powers of the falling water so estimated, and the mechanical effects produced by the wheel at the maximum, deduced from the mean of several of Mr. Smeaton's experiments, is as 3 to 2 nearly. We have before, in our observations upon the effects of undershot-wheels, shewn that the general ratio of the power to the effect, when greatest, was 3 : 1. The effect, therefore, produced by an overshot-wheel, under the same circumstances of quantity and fall of water, is at a medium, double that produced by an undershot. From this, it appears that non-elastic bodies, when acting by their impulse or collision, communicate only a part of their original power; the other part being spent in changing their figure in consequence of the stroke.

The ratio of the power to the effect, computed upon the height of the wheel only, was, at a maximum, as 10 : 8, or as 5 : 4 nearly, because Mr. Smeaton made the wheel of a less height than the fall of water, in order to allow some run or descent of the water through the spout or trough, which conducted it into the buckets of the wheel. We find the ratio, between the power and effect, to continue the same, in cases where the constructions are similar; hence we must infer, that the effects, as well as the powers, are as the quantities of water and perpendicular heights multiplied together respectively.

II. *On the most proper Height of the Wheel, in Proportion to the whole Descent.*—The preceding observation shews, that the effect which can be obtained from the same quantity of water, descending through the same perpendicular space, is double when it is made to act by its gravity upon an overshot-wheel, to what could be obtained from it when made to act by its impulse upon an undershot-wheel.

Hence it follows, that the higher the wheel is, in proportion to the whole descent, the greater will be the effect; because an overshot-wheel depends less upon the impulse of the water when it first strikes the wheel, and more upon the gravity of the water in the buckets. The water which is conveyed into the buckets can produce very little effect by its impulse, even if its velocity be great; both on account of

the obliquity with which it strikes the buckets, and in consequence of the loss of water occasioned by a considerable quantity of fluid being dashed over their sides. Instead, therefore, of expecting an increase of effect from the impulse of the water occasioned by its fall through some part of the whole height, we should cause it to act through as much as possible of this height by its gravity, by making the diameter of the wheel as great as possible. But a disadvantage attends even this rule; for if the water is conveyed into the buckets with a very small velocity, which must be the case when the diameter of the wheel equals the height of the fall, the velocity of the wheel will be retarded by the impulse of the buckets striking against the water, in order to put it in motion, and much power would be lost by the water dashing over them. In order, therefore, to avoid all inconveniences, the distance of the spout from the receiving-bucket should, in general, be about two or three inches, that the water may be delivered with a velocity a little greater than that of the wheel; or, in other words, the diameter of an overshot-wheel should be two or three inches less than the greatest height of the fall; and yet it is no uncommon thing to see the diameters of these wheels scarcely one-half of that height. In such a construction, the loss of power is prodigious.

It is always desirable that the water should have somewhat greater velocity, than the circumference of the wheel in coming thereon, otherwise the wheel will not only be retarded by the buckets striking the water, but thereby dashing a part of it over so much of the power is lost.

The velocity that the circumference of the wheel ought to have, will be known by what we shall say next, and the depth of column requisite to give the water its proper velocity, is easily computed from the rules and tables given in this article, and will be found much less than what is generally supposed.

This maxim obliges us to use a wheel, whose diameter is nearly equal to the whole fall; but we shall not gain any thing by employing a larger wheel. It is true, we could then apply the water upon a part of the circumference where the weight will act more perpendicularly to the radius, but we should lose more, by the necessity of discharging the water at a greater height from the bottom, because the water, in all cases, begins to run out of the buckets long before they arrive at the bottom of the wheel.

Suppose the buckets of both wheels equally well constructed in either case, whether the wheel is only as high as the fall, or of a greater height, then the heights above the bottom, where they will discharge the water, will increase in the proportion of the diameter of the wheel. That we shall lose more by this, than we gain by a more direct application of the weight, is plain without any further reasoning, by taking the extreme case, and supposing our wheel enlarged to such a size, that the useless part below would be equal to our whole fall. In this case, the water would be spilled from the buckets as soon as it is delivered into them. All intermediate cases, therefore, partake of the imperfection of this. It was the object of Mr. Buchanan's bucket-wheel, which we have already described, to avoid this difficulty, and employ a height of fall which bore only a small proportion to the whole height of the wheel. This observation necessarily leads us to consider the best form for the buckets.

III. *On the best Form for the Buckets of overshot Wheels.*—It is impossible to construct the buckets so that they will remain completely filled with water till they reach the bottom of the wheel: indeed, if the buckets were formed by partitions directed to the axis of the wheel, the whole water

must run out by the time they have descended to the level of the axis; and, in consequence, there must be a great diminution in the mechanical effect of the wheel. Millwrights have, therefore, turned their chief attention to the determination of a form for the buckets which shall enable them to retain the water through a great portion of the circumference of the wheel. An inspection of *figs. 2 and 3* will shew at once the proper form which has been established by long practice. These are called elbow-buckets, because each partition is formed by two boards, which are put together with an angle or elbow. The rule for setting these out is, to divide the wheel into the number of buckets it is intended to have; then take four-fifths of the space or interval between two partitions for the depth of the shrouding, that is, the breadth of the circular rings at the sides of the wheel, which form the ends of the buckets, and are called the shrouds; whilst the planking, which forms the bottom of all the buckets, is called the sole of the wheel. That board of each partition which is in the direction of a radius to the wheel, rises from the sole half the depth of the shroud; the other board of the bucket is so inclined, that its outer end shall be advanced beyond the line of the next radius-board, if it was produced.

It is a great advantage to make the partitions of the buckets thin, particularly the edges of the partitions, which will meet and divide the stream of water flowing upon the wheel; and if these edges are not made sharp, they will splash the water about; the edges are, therefore, finished by iron-plate, or it is better to make all the inclined parts of the partition of iron-plate. The greater number of buckets, and the shallower they are, the more regularly the wheel will act. The limits are, that the mouths of the buckets shall be of such width as to allow the air to escape, at the same time that the stream of water flows in; and also that the breadth of the wheel shall not be extravagantly great, to make its buckets contain as much water as would produce the power required from the wheel.

The loss of water, at the lower part of the wheel, will very much depend upon the proportion of water which is poured into each bucket. It is evident, that if the buckets, of whatever form they are made, were totally filled when at the top of the wheel, they must begin to spill the water immediately when they departed from that position. But, on the other hand, if only a part of the content of each bucket is filled with water, then it will bear a greater degree of inclination, and be a longer time before the water will begin to spill from the bucket. This is a reason for making large buckets, and filling only a part of their contents. In practice a medium must be struck between these contending circumstances, and the wheel will act to advantage.

It has been proposed to apply another bend to the partition-boards of each bucket which shall be beyond the inclined board that we have described, and shall be concentric with the rim of the wheel, in the same manner as is represented in Mr. Buchanan's wheel, *fig. 5*. It is true that this form would retain the water from spilling for a longer time, and thus be an advantage; but it is not favourable for admitting the water into the buckets when at the top of the wheel.

The inclined boards, when made as we have described, may be exactly in the line of the stream of water, which issues from the spout when it passes beneath such stream; and in this way, if the edge of the inclined board is made thin, there will be as little splashing of the water as possible. But by the addition of another part to the edge of the partition, which is concentric to the circle of the wheel, the stream of water cannot be made to proceed exactly in the line

line of the partition, and will therefore splash the water. The splashing may appear immaterial, but it is in reality very prejudicial, because the broken water fills the mouth of the bucket, and prevents the air from getting out readily, and it is for this reason that it is very necessary to allow so much of the fall above the height of the wheel, as will make the water run into the buckets, with a little greater velocity than the motion of the wheel.

Dr. Robinson, in the *Encyclopædia Britannica*, described a plan for the buckets of an overshot wheel, which was invented by Mr. Robert Burns, millwright, and executed by him at a cotton-mill in Scotland: it is shewn in *fig. 5. Plate II. Water-wheels*. In this way, the wheel has two ranks of buckets, one within the other. The buckets consist of a partition A B, in the direction of a radius of the wheel, which is joined to another B C, inclined to that, and also to a third C D, which is concentric with the rim of the wheel.

The bucket is divided into two, by a partition L M, also concentric with the rim of the wheel, and so placed as to make the inner and outer portions of the bucket nearly of equal capacity. It is evident, without any farther reasoning, that this partition will enable the double bucket to retain its water much longer than the single one could. When they are filled only one-third, they retain the whole water at eighteen degrees from the bottom of the wheel, and they retain half of the water at eleven degrees. The only objection is, that they do not admit the water quite so freely as buckets of the common construction.

This arises from the air, which must find its way out to admit the water, but is obstructed by the entering water, and occasions a great spluttering at the entry. This may be entirely prevented, by making the spout considerably narrower than the wheel, and will leave room at the two ends of the buckets for the escape of the air. It was found in practice, that a slow moving wheel, allowed one half of the water to get into the inner buckets, especially when the partitions which form the inner buckets, did not altogether reach the radius drawn through the lip D of the outer bucket. The doctor considers this as a very great improvement of the bucket-wheel; and when the wheel is made of a liberal breadth, so that the water may be very shallow in the buckets, it seems to carry the performance as far as it can go. Mr. Burns made the first trial on a wheel of twenty-four feet diameter, and its performance is manifestly superior to that of the wheel which it replaced, and which was a very good one. It has also another valuable property. When the supply of water is very scanty, a proper adjustment of the stream of water issuing from the spout, will direct almost the whole of the water into the outer buckets; which, by placing it at a greater distance from the axis, makes some addition to its mechanical energy.

IV. *Concerning the proper Velocity of the Circumference of an overshot Wheel, in order to produce the greatest Effect.*—If a body of water is let fall freely from the surface of the water in the upper reservoir to the bottom of the descent, it will take a certain time in falling; and in this case, the whole action of gravity will be spent in giving the water a certain velocity. But if this water in falling is intended to act upon some machine, so as to produce a mechanical effect, the falling water must be retarded, because a part of the action of gravity is then spent in producing the effect, and the remainder only will give motion to the falling water, which motion it will retain, after it has quitted the machine. On this principle, the slower a body descends the greater portion of the action of its gravity can be applied to pro-

duce mechanical effect, and in consequence the greater that effect will be.

If a quantity of water falls from a stream, into each bucket of an overshot-wheel, it is there retained until the wheel, by moving round, discharges it. Now, the slower the wheel moves, the more water each bucket will receive, because it remains a longer time beneath the spout, so that what is lost in the speed with which the wheel moves, is gained by the pressure of a greater quantity of water acting in the buckets at once; and if considered only in this light, the mechanical power of an overshot-wheel to produce effects will be equal, whether it moves quick or slow. The popular reasoning adduced to prove this has been of the following kind. Suppose that a wheel has thirty buckets, and that four cubic feet of water are delivered in a second on the top of the wheel, and discharged, without any loss by the way, at a certain height from the bottom of the wheel.

It is clear that this stream will supply the same quantity, whatever is the rate of the wheel's motion; and the buckets must be of a sufficient capacity to hold all the water which falls into them when the wheel moves very slow. Suppose this wheel employed to raise a weight of any kind, for instance to draw a basket of coals out of a deep pit or mine, and that the rope winds upon a barrel of such size that the basket will be drawn up with the same velocity as the water in the buckets descends. Suppose, further, that the wheel will make four revolutions in a minute, or one turn in fifteen seconds, when the load or weight in the basket which forms the resistance to the motion of the machine is one-third of the load of water contained in the buckets of the wheel.

Now, during the time of one revolution, sixty cubic feet of water will have flowed into the thirty buckets, and each have received two cubic feet. In this case, the basket may contain a weight equal to twenty cubic feet of water, which weight will be drawn up a height equal to one circumference of the wheel, during one turn of the wheel, or in fifteen seconds of time.

Now suppose the machine so loaded, by making the basket more capacious, that the wheel can only make two turns in a minute, or one turn in thirty seconds, then each descending bucket of the wheel will receive four cubic feet of water. If the basket contained a double weight, *viz.* equal to forty cubic feet, the effect produced by the machine would be the same as before, because the velocity is only one half; but we find in practice, that it will raise more than in this proportion when it moves slower, for if we attend to what we have just observed of the falling body, we find that so much of the action of gravity as is employed in giving motion and velocity to the wheel and water therein, must be subtracted from its pressure upon the buckets. The product made by multiplying the number of cubic inches of water which act on the wheel at once by its velocity, will be the same in all cases; yet, as each cubic inch, when the velocity is greater, presses more lightly upon the buckets than when the velocity is less, the power of the water to produce effects will be greater in the less velocity than in the greater. This leads us to the general rule, that the less the velocity of the wheel, the greater will be the effect produced by any given quantity, and fall of water.

A confirmation of this doctrine, together with the limits it is subject to in practice, is a matter of experiment and observation which has been ably decided by Mr. Smeaton. The velocity of the wheel should not be diminished, further than what will produce some solid advantage in point of power; because, as the motion is slower, the buckets must be made larger, that the increase of their weight may compensate

penfate for the flownefs of their motion. The wheel being thus more loaded with water, the ftreffs upon every part of the work will be increafed in proportion.

The beft rule for practice will be, to make the velocity of the circumference a little more than three feet in a fecond.

Experience confirms, that this velocity of three feet in a fecond, is applicable to the greateft overfhot wheels as well as the fmalleft; and all other parts of the work being properly adapted to this velocity, the fall of a given quantity of water, will produce very nearly the greateft effect poffible. But it is alfo certain from experience, that large wheels may deviate further from this rule before they will lofe their power, by a given aliquot part of the whole, than fmall ones can be admitted to do; for inftance, a wheel of twenty-four feet high may move at the rate of fix feet *per* fecond, without lofing any confiderable part of its power. This may perhaps be accounted for, when we confider how fmall a proportion of the whole fall is requifite to give the water the proper velocity which the wheel ought to have; whilft in a fmall wheel, the fame height muft be allowed for that purpofe, and confequently, a greater proportion of the whole height. On the other hand, Mr. Smeaton tells us, that he had feen a wheel of thirty-three feet diameter that moved very ftadily and well, with a velocity but little exceeding two feet *per* fecond.

There is a natural wifh to fee a machine move briskly; it has the appearance of activity: but a very flow motion always looks as if the machine was overloaded. For this reafon, mill-wrights have always yielded flowly, and with reluctance, to the advice of Mr. Smeaton, but they have yielded; and we now fee them adopting maxims of conftruftion more agreeable to found theory, that is, making their wheels of great breadth, and loading them with a great deal of work. The reluctance to adopt this fystem did not arife folely from prejudice, but from a real inconvenience attending the flow motion of the wheel when the refiftance which is oppofed to its motion, and which is the caufe that it moves flowly, is not uniform in the different parts of a revolution.

In all machines, there are fmall inequalities of action which are unavoidable; and in fome machines very great inequalities arife, from the intermitting motions of cranks, flampers, and other parts which move unequally or reciprocally. When a water-wheel is employed to give motion to fuch machines, it may be fo refifted or loaded, as to be nearly in equilibrio with its work, in the moft favourable pofition of the parts of the machine; but when thefe change into a lefs favourable pofition, the machine may flop the wheel altogether, or at all events hobble, and work very irregularly. And for the fame reafon that a water-wheel accommodates its motion very quickly to the refiftance it is to overcome, fo all tendency to irregular motion is increafed. A wheel, when its load is increafed, moves more flowly, and receives more water into each bucket; thereby taking to itfelf a weight of water equal to overcome its load, and on the other hand by moving quicker, it takes lefs water into each bucket when the load is diminished. But thefe changes do not take place infтанtaneously, becaufe it can be only in the moment that each bucket paffes beneath the fream, that the fhare of water it fhall have, will be influenced by the rate of the wheel's motion. When a bucket is once filled it continues with that charge until it arrives at the bottom of the wheel.

This felf-regulating property of the wheel can only apply in cafes of fmall and permanent changes of refiftance,

for it always comes too late to correct fudden and confiderable changes in the refiftance; then it acts in the contrary direction. Suppofe, for inftance, an overfhot wheel is employed to work a fingle pump by means of a crank, the refiftance of this machine will be continually varying; it will be nothing during one-half of the period of the revolution when the pump is not drawing any water, and during the other half it will be in a confant ftate of increafe and diminution. Now, during the time this wheel has nothing to do, it will turn round very quickly, and therefore each bucket will receive very little water; confequently, when the wheel comes to be refifted, the wheel will have fo little water in its buckets, that it will perhaps be quite ftopped: in this cafe, the bucket beneath the fpout will receive water until it is quite full, and then the water will run over and fill fo many of the buckets beneath it, as to put the wheel in motion flowly; in confequence, the fucceeding buckets will receive a large fhare of water during the half revolution when the pump makes its ftroke; but when this is finifhed, and the refiftance ceafes, the wheel being well loaded with water, will in confequence move very rapidly for a half revolution, and its buckets will receive very little water.

This is indeed an extreme cafe of irregular refiftance, and muft be remedied by applying two pumps inftead of one, or a balance-weight, or a fly-wheel; but the fame principle will apply in cafe of fmall irregularities. In all cafes, the refiftance muft be reduced to a great degree of uniformity, before a water-wheel can be applied to it with advantage, particularly if the wheel is intended to move flowly, with a view of obtaining the greateft power, the irregularities will then have more ferious confequences.

A little more velocity enables the machine to overcome thofe increafed refiftances by its *inertia*, or the great quantity of motion inherent in it. Great machines poffefs this advantage in a fuperior degree, and will confequently work ftadily with a fmall velocity. In all cafes, the machine muft have fo much moving matter in it as is fufficient to overcome the irregularities, and regulate the motion of the wheel. If this is not already found in the machine, as in the mill-ftones of a corn-mill for inftance, the weight muft be placed in the water-wheel itfelf, or in a fly-wheel applied for the purpofe.

Mr. Bucharan meafured the quantity of water which a cotton-mill required, when going at its common velocity; and when going at half that velocity. The refult was, that the laft required juft half the quantity of water which the firft did. In the experiments, the quantities of water were calculated from the depth of water and apertures of the fluires.

From which experiments, he inferred that the quantity of water neceffary to be employed in giving different degrees of velocity to a cotton-mill, muft be nearly as the velocity. The water from the cotton-mill on which he made the obfervation, falls a little below it, into a perpendicular-fided pond, which ferves as a dam for a corn-mill. By meafuring the time which the water took to rife at a certain height in that pond, he determined the expediture of water when the corn-mill moved at its common velocity; and alfo when it moved at nearly half that velocity.

The refult of thefe experiments approached very nearly to the former, and all the differences could be accounted for, by a fmall degree of leakage, which took place at the fluires on the lower end of the pond; and the time being greater when the mill moved flowly, the leakage would of courfe be greater.

In these experiments, the motion of the water-wheel being exactly proportioned to the quantity of water expended, the load upon the wheel must have been equal when it moved quick or slow, that is to say, the buckets must have been equally filled when the wheel moved at its ordinary motion, or at half that motion.

The effect, therefore, of letting more water on a wheel when the resistance continues the same, is not to lodge a greater quantity in each of the buckets, but to supply the same quantity to each bucket when the wheel is in a greater motion.

The greatest velocity that the circumference of an overshot wheel can acquire, depends jointly upon the diameter or height of the wheel, and the velocity of falling bodies; for it is plain, that the velocity of the circumference can never be greater, than to describe a semicircumference, in the time that a body let fall from the top of the wheel would descend through its diameter, nor indeed quite so great; as a body descending through the same perpendicular space cannot perform its course in so small a time, when passing through a semicircle, as would be done in a perpendicular line. Thus, if a wheel is sixteen feet one inch diameter, a body will fall through the line of its diameter in one second: this wheel, therefore, can never arrive at a velocity equal to the making one turn in two seconds. An overshot wheel can never come near this velocity, for when it acquires a certain speed the greatest part of the water is prevented from entering the buckets; and the rest, at a certain point of its descent, is thrown out again by the centrifugal force. The velocity, when this action will begin to take place, depends in a great degree upon the form of the buckets as well as other circumstances; so that the utmost velocity that an overshot wheel may be capable of is not to be determined generally; and indeed the knowledge of it is not at all necessary in practice, because a wheel, in such case, would be incapable of producing any mechanical effect.

V. *On the proper Load for an overshot Wheel, in order that it may produce a maximum Effect.*—The maximum load or resistance for an overshot wheel, is that which will reduce the circumference of the wheel to its proper velocity, of three or three and a half feet *per* second; and this will be known, by dividing the effect it ought to produce in a given time, by the space intended to be described by the circumference of the wheel in the same time; the quotient will be the resistance to be overcome at the circumference of the wheel, and is equal to the load required, the friction and resistance of the machinery included.

VI. *On the greatest Load that an overshot Wheel can overcome.*—The greatest load an overshot wheel can overcome depends upon the magnitude of the buckets; and the resistance which will stop the wheel, must be equal to the effort of all the buckets in one semicircumference, when quite filled with water.

The structure of the buckets being given, the quantity of this effort may be assigned, but is not of much importance in practice, as in this case also, the wheel loses its power; for though the water makes the utmost exertion of gravity upon the wheel, yet, being prevented by a counterbalance from moving at all, it is not capable of producing any mechanical effect, according to our definition. An overshot wheel, generally ceases to be useful before it is loaded to that pitch, for when it meets with such a resistance as to diminish its velocity to a certain degree, its motion becomes irregular; yet this never happens until the velocity of the circumference is reduced to less than two feet *per* second, where the resistance is equable, as appears not

only from the preceding specimen, but from experiments on larger wheels.

VII. *Construction of the Pentrough for supplying the Water to overshot Wheels.*—We have hitherto spoken of the stream of water, as if it issued from a spout nearly in an horizontal direction, or with only so much inclination as will make the line of the stream correspond with the direction of the oblique part of the bucket-board. This is the ancient, and still the common way; Mr. Smeaton's, which is a much better, is shewn in *fig. 2. Plate I. Water-wheels.* G represents the pentrough through which the water flows, and F F strong cross-beams on which it is supported; the wheel is situated very close beneath the bottom of the trough, as the figure shews. E E are two arms of the wheel, which are put together, as shewn in *fig. 7.* DB is the wooden rim of the wheel; the narrow circle beyond this is the section of the sole planking, and on the outside of this the bucket-boards are fixed as the figure shews; one of the bottom boards, *b*, of the trough at the end is inclined, and an opening is left between that end and the other boards of the bottom, to let the water pass through; this opening is closed by a sliding shuttle, *c*, which is fitted to the bottom of the trough, and can be moved backwards and forwards by a rod, *d*, and lever, *e*, which is fixed into a strong axis *f*; this axis has a long lever on the end, which, being moved by the miller, draws the shuttle along the bottom of the trough, and increases or diminishes the aperture through which the water issues. The extreme edge of the shuttle is cut inclined, to make it correspond with the inclined part *b*, and by this means it opens a parallel passage for the water to run through, and this causes the water to be delivered in a regular and even sheet; and to contribute to this the edges of the aperture where the water quits it, are rendered sharp by iron plates; the shuttle is made tight where it lies upon the bottom of the trough by leather, so as to avoid any leakage when the shuttle is closed. When the wheel is of considerable breadth, the weight of the water might bend down the middle of the trough until it touched the wheel; to prevent this, a strong beam, O, is placed across the trough, and the trough is suspended from this by iron bolts which pass through grooves in the shuttle, so that they do not interfere with the motion of the shuttle.

Fig. 3. of the same plate is an overshot wheel, for which Mr. Nouaille took a patent in 1813; he recommends that the water-wheel be made the full height of the fall of water, and that the water be applied upon the wheel at 53 degrees from the vertex. The pentrough is made nearly on the same plan as Mr. Smeaton's. O R is the trough, *bg* the end inclined in the direction in which the water is intended to be directed, *f* the shuttle, sliding horizontally on the bottom of the trough, *cde* the lever for drawing the shuttle, to which motion is given by a regulating screw *a* and nut *b*.

Fig. 9. Plate II. Water-wheels, is the method of laying on water, which has for several years been in common use in Yorkshire and the north of England. In this the water is not applied quite at the top of the wheel, but nearly in the same position as the last described; but the advantages of this wheel over all others is, that the water can be delivered at a greater or less height, according to the height at which the water stands in the trough; but in all the preceding methods if the water is subject to variations of height, as all rivers are, then the wheel must be diminished, so that in the lowest state of the water it will stand a sufficient depth above the orifice in the bottom of the trough to issue with a velocity rather greater than the motion of the wheel. In this case, when the water rises to its usual height, or above it, the increase of fall thus obtained is very little advantage to the wheel; the improved wheel

wheel can at all times take the utmost fall of the water, even when its height varies from three to four feet. A A is the pentrough made of cast-iron; the end of it is formed by a grating of broad flat iron bars, which are inclined in the proper position to direct the water through them into the buckets of the wheel. The spaces between the bars are shut up by a large sheet of leather, which is made fast to the bottom of the iron trough at *a*, and is applied against the bars; and the pressure of the water keeps it in close contact with the bars, so as to prevent any leakage. This is the real shuttle, and to open it so as to give the required stream of water to the wheel, the upper edge of the leather is wrapped round a smaller roller *b*; the pivots at the ends of this roller are received in the lower ends of two racks, which are made to slide up and down by the action of two pinions fixed upon a common axis which extends across the trough; this axis being turned, raises up or lowers down the roller, and the leather shuttle winds upon it as it descends, or unwinds from it as it ascends, so as to open more of the spaces between the bars, or close them as it is required. In order to make the roller take up the leather, and always draw it tight, a strap of leather is wound round the extreme ends of the rollers, beyond the part where the leather shuttle rolls upon it. These straps are carried above water and applied on wheels, which wind them up with a very considerable tension by the action of a band and weight wrapped on the circumference of a wheel, which is on the end of the axis of those wheels.

The water runs over the upper side of the roller, and flows through the spaces between the grating into the buckets of the wheel; the descent of the water passing through the bars, and afterwards in falling before it strikes the bottom of the bucket, is found fully sufficient to produce the necessary velocity of the water, for a fall of four inches produces a velocity of more than four feet *per* second.

We recommend this as the best method of applying the water, as we see in all other forms that a much greater portion of the fall is given up in order to make the water flow into the wheel; not that any such depth as is commonly given is at all necessary, but the aperture in the trough must be placed so low that the water will run through it in the very lowest states of the water, otherwise the wheel must stop at such times.

On the Manner of framing Water-wheels.—The weight of every wheel must be supported by its axis, which therefore demands the first consideration. If the axis is to be of wood it should be made of a tree of hard and durable wood, of a length and size proportioned to the size and weight of the wheel; into each end a gudgeon or centre should be fixed for the wheel to turn upon. There are two methods of fixing the gudgeon into a wooden axis; one is, by forming the gudgeon with a cross, which is let into the end of the tree, and fastened by screws, and the wood is compressed round the cross by two or three iron hoops, fitted on the end of the tree and wedged; this is explained in the article *MILL-Work*. The other method is, to make a strong iron box in a piece with the gudgeon, into which box the end of the tree is received and secured by wedges. The box being of an octagon shape, and the wood being cut to the same figure, it cannot slip round within the box.

Of late years it has been usual to make the great axis of water-wheels of cast-iron, which is a very good plan, provided the axis is made of sufficient dimensions. This was first practised by Mr. Smeaton, but he was rather unfortunate, as several of them broke after having been many years in use: he then employed hollow tubes of cast-iron of large dimensions and considerable thickness of metal. Even

now that the strength of cast-iron is better understood, it is not uncommon for the axis of a water-wheel to break, particularly in cold and frosty weather, and for this reason some millwrights use wrought iron, but the hollow tube is so much stronger, as to be very secure from accident.

In an iron axis it is advisable to make the bearings of the axis close to the sides of the water-wheel, and leave the ends of the axis projecting beyond the bearings, in order to attach the cog-wheel, by which the power of the wheel is to be communicated to other machinery. This diminishes the length of the axis between the bearings, and renders it much stronger; wooden axes must have the gudgeons at the extreme ends.

The next point to be considered is, the best means of affixing the arms of the wheel firmly to the axis. If the arms are of wood, and the axis also, the most obvious plan is to mortise the arms into the axis; but this is the worst method that can be adopted, because the axis is much weakened, and the water being admitted into the centre of the tree causes it soon to decay, nor can an arm be easily replaced without taking all the wheel to pieces.

A better way is to use eight timbers for the arms, and put them together so as to intersect each other at right angles, (as is shewn in *fig. 7. Plate I.*) leaving a square opening in the centre for the reception of the axis, which is made up to a square by adding pieces of wood to it, and the wheel is fastened on by wedges. The only objection to this is, that the arms are weakened by intersecting each other, and they support the circular rim of the wheel in unequal segments.

In Mr. Buchanan's water-wheel, which we have before described in *figs. 4 and 5, Plate I. Water-wheels*, is a particular construction of the arms formed by thin planks of wood. He states that this plan is applicable to any kind of water-wheel; and since 1790, when he first constructed a wheel with arms on that principle, a considerable number of large wheels have been erected in Scotland on the same plan. It is evident that arms, such as are commonly fixed in mortises in the axis, are weakest in one direction, and that commonly in the direction of the strain. To remedy this defect the feather-pieces FF are applied all round, having their broadest ends towards the centre of the wheel, and being at right angles to the breadth of the principal arms. In order to unite them strongly to the principal arms, and connect the whole more firmly together, a ring of iron, R, is applied on each side; blocks of wood being put in the vacant spaces between, and the keys or wedges, K K, bind the whole close to the axis.

The very best method of uniting the arms to the axis is to have a cast-iron centre-piece, or strong hoop, to fit on the wooden axis with a broad projecting flanch round it, against the flat surface of which the arms of the wheel are applied, and the intervals between them filled up by wooden blocks or wedges; the arms and blocks are firmly bound to the iron flanch by iron rings applied to the arms on the opposite side to the flanch, with screw bolts to go through the whole. This same plan is applicable to an iron axis, and will be more clearly understood by a reference to the article *MILL*, and *Plate XXXIV. Mechanics*; but it is there described that the broad circular flanch to screw the arms against, is cast in the same piece with the axis. This was Mr. Smeaton's original plan, but the flanch should be made in a separate piece, and fastened on the axis with wedges; for if cast in the same piece, the contraction of the metal contained in the flanch when cooling, renders the metal of the axis spongy at the part where it joins to the flanch, and causes them to break at that part. Sometimes the cast-iron centre-piece is made with a distinct

distinct cell to receive each arm, and they are fastened into the cells by wedges and screw-bolts, but a flat flanch with the intervals filled up by blocks is more simple and secure. Modern wheels are very frequently made with cast-iron arms, which in this case are attached to the axis by a similar centre-piece.

The circular rims of water-wheels are commonly made of wood, put together in two or three thickneses, the joinings of one ring not coinciding with those of the other, and 8 or 10 segments in each thicknes, according to the size of the wheel; the thickneses are united together by rivets. The arms are attached to the ring by notching them in, and securing them by bolts. Cast-iron rings are now generally used, and with great advantage, because the necessary mortises can be made in iron, without weakening the ring; but the strength of a wooden ring is greatly impaired by the mortises through it.

The number of rings in a wheel depend upon its breadth; when the wheel is four feet wide, two rings will support the float-boards or buckets, but the rings should not be more than five feet asunder, or the floats may bend and yield; for want of a sufficient support each ring is framed with its set of arms, so that every one derives its strength from the axis. When a wheel is of great breadth, the whole will be very much strengthened, by applying oblique braces, extending from the centre-pieces of the outside rings to the circumference of the middle ring, by firmly attaching these oblique braces to the arms of all the rings which they intercept; they form truss-frames which prevent the wheel and the axis from bending by its weight: this is particularly useful in wide overshot wheels.

In breast and undershot wheels the float-boards are nailed to pieces of wood called starts, which are fixed into the mortises in the rings, and project outwards for that purpose.

In overshot-wheels, the rings of the wheels are covered by boards laid parallel to the axis, well jointed together, and spiked down to the rings like the boards of a floor to the joists. This boarding forms a close cylinder, which is called the sole of the wheel, and is the foundation for the buckets. When the rings of the wheel are of iron, holes are left in the castings in the edge of the rings, at regular distances round the circumference, and these are filled up with plugs of wood, into which the nails can be driven to fasten on the boarding of the sole. The sole of the wheel is sometimes made of iron plates rivetted together, and rivetted also to the rings of the wheel.

At the ends of the sole-boards, two circular rings of wood or iron, called shrouds, are fitted on perpendicularly to the sole to form the ends of the buckets; and it is usual, if the wheel is wide, to apply a shrouding over each ring of the wheel, and then the buckets are divided into lengths of about four or five feet. In the flat surfaces of the shroudings, grooves are made for the reception of the ends of the bucket-boards. It is usual to make the first board, which is in the direction of a radius, of wood, and the outside one is generally made of iron plate; but sometimes the whole are made of plate iron, and both parts of the buckets are then bent up out of one piece, and the ends of the plate; and also that part of the edge which is to apply to the sole, is turned square to lie flat against the sole and the shrouding, so that rivets and nails may unite all together, and make water-tight joints.

When the shrouding is of cast-iron, it is made to serve instead of the rings of the wheel, because it has sufficient strength to serve both purposes: the arms of the wheel are in this case applied flat against the ring of shrouding, and bolted to it.

The breast-wheel, *fig. 3. Plate II. Water-wheels*, at Messrs. Strutt's works, which we have already noticed, is deserving of further notice from the manner of putting it together. The rings of the wheel are made of cast-iron, and the float-boards are included between the rings in the manner of an overshot wheel, but the arms are only of wrought iron, being made of small round iron rods, which are very light, and have little strength to resist bending; but as they are all tied in from the centre, the ring cannot deviate from its true circular figure, and to sustain the wheel sideways, oblique bars are extended from the centre-pieces at each end of the axis, and are united to the circular ring in the middle of its breadth, which is 15 feet. We have seen two overshot-wheels of 24 feet diameter, and 9 feet broad, made in the same way. It is plain that in this construction the axis of the wheel can do no office but to support the weight of the wheel; for though these arms are sufficiently strong for that purpose, they can have little strength by way of levers to transmit the force of the circular motion of the rim of the wheel to the axis; but the power is transmitted in a better way than from the axis, *viz.* by a ring of cogs screwed to the circular rim of the wheel, and working in a pinion which conveys the motion to the mill. There is another similar ring of cogs at the other side of the wheel, which works into a pinion fixed on the same shaft, by this means nearly all the strain is taken from the axis of the water-wheel; for the pinion is placed on the descending side of the wheel, so that the weight of the water acting on the float-boards is immediately transmitted to the pinions by the strength of the rings of the wheel.

This method of transmitting the power is also applied to other wheels than those which are made with slight arms like the above; the ring of cogs is sometimes placed in the middle of the breadth of the wheel, and then acts upon one pinion, but it is much better to place it at one side or both sides, if the wheel is very broad, because the circle of the teeth may then be made rather less than the diameter of the rings of the wheel, and the side of the ring being closely fitted to the stone-work of the race, the water may be excluded from the cogs.

It is obvious that of the various constructions of water-wheels, that is the strongest which communicates its motion by means of a ring of cogs immediately attached to its rim, where the power of the water is also applied, the least possible strain being thus thrown on its arms and axis.

The only objection to this plan is, that as the teeth of the cog-wheel are in most cases constantly wet, which prevents the grease from adhering, the usual mode of occasionally greasing the cogs is of little or no use, and the dirt in the water grinds away the teeth; or, were the water even free from dirt, there would be much unnecessary friction and waste of power.

Greasing Machine for the Cog-Wheel of a Water-Wheel.—Mr. Buchanan mentions two water-wheels of this kind, in which the rings of the teeth were wearing very fast, and knowing the trouble and expence of renewing them, he was solicitous to discover some means of rendering them more durable. The only way which presented itself was by some contrivance to keep them well greased.

This he did by a machine shewn in *fig. 8. Plate I. Water-wheels*; it is nothing more than a kind of pinion, with one or more of its teeth made hollow to contain the greasy substance, and the metal plate of which the hollow cog is composed is perforated with small holes, for exuding the grease through those parts which come in contact with the teeth of the wheel.

Fig. 8. is a section of the greasing machine; A B represents part of the ring of teeth on the circumference of the

water-wheel. The greasing-pinion which works in these teeth is mounted on an axis, as is clearly shewn.

N O a retarding lever, of which N is the fulcrum, and O a weight to make it press on the axis of the greasing-pinion, so as to cause a resistance, and make the cogs of the wheel press forcibly on the cogs of the pinion.

G H I K, the hollow teeth for containing the grease; they are made of copper-plate or iron; and to make the perforated sides of the greasing leaves come in close contact with the face of the teeth of the wheel, the lever N O, with a small weight on it, acts on a pulley fixed on the axle of the pinion, and serves to retain it.

E F, &c. the solid teeth of the pinion, made of wood; there are sliders which open for admitting the grease into the hollow teeth at their ends.

The number of leaves in the greaser should be such, that those containing the grease shall apply themselves in the course of several revolutions of the wheel to each of its teeth. Mr. Buchanan found a greaser of 12 leaves, 4 of which contained grease, had this effect upon a wheel of 304 teeth; and one of 13 leaves, with one tooth only filled with grease, served a wheel of 168 teeth.

It is best to use a mixture of tallow, oil, and black lead for greasing, made of a consistency to feed regularly, and freshened about twice in a week.

Construction of a Breast-Wheel of very great Width.—At Messrs. Strutt's works is a very powerful breast-wheel, made of the extraordinary width of 40 feet, and it deserves our notice from the manner of framing it together; its diameter is only 12½ feet, and it is made without any axis, or rather the axis is hollow, and so large that the float-boards are fixed immediately upon it. It is made like a very long cask, 48 feet long, composed of 32 staves of six inches thickness, bound together by hoops like an ordinary cask; it is five feet in diameter at one end and six feet at the other, and in the middle 7 feet 2 inches; the small end is made up solid for three feet in length, and the gudgeon is fixed in this solid part; the larger end is solid for four feet from the end, and on this part the large cog-wheel is fixed to communicate the motion to the mill; it is 14 feet diameter, and has 120 cogs, whilst the water-wheel is only 12½ feet diameter to the outside of the floats. The floats are supported by 10 circular rings, which are fixed on the outside of the axis or cask, at four feet distance from each other, and the float-boards are fixed between these rings, 24 floats being arranged in each circle; but the floats in the different spaces are not made to line with each other, because if the water was to strike upon the whole length of 40 feet of float-board at once, it would give a sensible shock to the water-wheel, and work the mill irregularly; hence the floats between all the different rings are placed opposite to the intervals between the floats in the adjoining spaces, by which means the water acts on the floats in rapid succession, so that the stroke upon any one float is imperceptible.

The float-boards are not made to touch the central-barrel or axis within two inches, in order to leave space for the air to escape. The float-boards in the middle of the wheel are 2 feet 4 inches wide, and at the ends are wider. This wheel has two shuttles, one above the other, like the breast-wheel before described in *fig. 3*, and the same dimensions; for the wheel is placed in the same mill, but is adapted to work when the tail-water rises in time of floods to such a height as to prevent the other wheel from working.

A very large overshot Wheel.—The largest overshot water-wheel of which we have heard, is that at Mr. Crawshaw's iron-works at Cyfarthfa, near Merthyr Tydvil, in South Wales: it is used to blow air into three of the large blast

furnaces for smelting iron; the water-wheel is fifty feet in diameter and six feet wide: it is chiefly made of cast iron, and has 156 buckets. The axis is a hollow tube, and is strengthened by twenty-four pieces of timber applied round it. On each end of the axis is a cog-wheel of twenty-three feet diameter, which turns a pinion. On the axis of these are two cranks, and a fly-wheel twenty-two feet diameter, and twelve tons weight; each of the cranks gives motion to a lever, like that of a large steam-engine, and works the piston of a blowing cylinder or air-pump 52½ inches in diameter, and five feet stroke, which blows air into the furnace, both when the piston goes up and down. The work on the other side being the same, it actuates in the whole four of these double cylinders; the wheel makes about two and a half turns *per minute*, and each cylinder makes ten strokes. It is called *Æolus*, and was built in 1800 under the direction of Mr. Watkin George.

At Aherdare, in South Wales, is an immense double water-wheel, consisting of two wheels of forty feet in diameter, placed one above the other like the figure 8, (see our article *CANAL*;) the water from the upper one actuating the lower one, and both being connected together by cog-wheels on their respective rings. We understand this machine has not answered, and we only mention it as an attempt to occupy a fall of water of eighty feet; in such cases, the *Pressure-engine*, described under that article, is a better method, particularly if the work will admit of a reciprocating motion.

Chain of Buckets.—This is applicable in many situations where there is a considerable fall of water. This sketch was taken from one in Scotland used to give motion to a thrashing-mill; the *fig. 6. Plate I.* is so obvious as to need little explanation. The buckets C, D, G, H, &c. must be connected by several chains to avoid the danger of breaking, and united into an endless chain, which is extended over two wheels A and B, the upper one being the axis which is to communicate motion to the mill-work; E is the spout to supply the water. The principal advantage of this plan is, that no water is lost by running out of the buckets before they arrive at the lowest part, as is the case with the wheel. Another is, that the buckets being suspended over the wheel A of small diameter, it may be made to revolve more quickly than a wheel of large diameter, and without increasing the velocity of the descending buckets beyond what is proper for them. This saves wheel-work when the machine is to be employed, as in a thrashing machine to produce a rapid motion. On the other hand, the friction of the chain in folding over the wheel at the top, and seizing its cogs, will be very considerable; these cogs must enter the spaces in the open links between the buckets, to prevent the chain slipping upon the upper wheel. We think this machine might be much improved by contriving it so, that the chain would pass through the centre of gravity of each bucket, whereas in the present form, the weight of each bucket tends to give the chain an extra bend.

The *Chain-Pump reversed* has been proposed as a substitute for a water-wheel when the fall is very great, and we think it would answer the purpose with some chance of success. It would have an advantage over the chain-pump when employed for raising water, in the facility of applying cup leathers to the pistons on the chain, in the same way as other pumps, which leathers expand themselves to the inside of the barrel, and are kept perfectly tight by the pressure of the water. In the chain-pump such leathers cannot be employed, because the edges of the leather-cups would turn down and stop the motion, when the cups were drawn upwards into the barrel. It is the defective mode of leathering the pistons of the chain-pump which occasions its great friction. In the motion of a machine of this kind

WATER.

the pistons would descend into the barrel, and might therefore be leathered with cups like other pumps, so as to be quite tight without immoderate friction. This machine was proposed by a Mr. Cooper in 1784, who obtained a patent for it, and Dr. Robison has again proposed it with recommendation.

Mechanism for equalizing the Motion of Water-Wheels.—When a part of the machinery of a mill is suddenly detached from the first mover, or suddenly connected with it, the load of the machine is either increased or diminished; and the moving power remaining the same, an alteration in the velocity of the whole will take place; it will move faster or slower. Every machine has a certain velocity, at which it will work with greater advantage than at any other speed; hence the change of velocity arising from the above cause, is in all cases a disadvantage, and in delicate operations exceedingly hurtful. In the case of a cotton mill, for instance, which is calculated to move the spindles at a certain rate, if from any cause the velocity is much increased, a loss of work immediately takes place, and an increase of waste from the breaking of the threads, &c.; on the other hand, there must be an evident loss from the machinery moving too slow. In steam-engines this evil is remedied by a contrivance called a governor, which we have already described in our article *STEAM-Engine*.

Governors are sometimes applied to water-wheels, and made on various constructions. Smith-bellows have been applied to that use, the upper board rising and falling on any augmentation or diminution of the velocity of the lower board, which received its motion from the mill, and forced air into the space beneath the upper board; from this space the air was permitted to escape by a pipe with a cock. If the lower board worked faster than the air could escape, the upper board would rise, but if it moved slower, then the board would sink; and this rising and falling was applied to regulate the shuttle of the water-wheel, not by the force of the bellows alone, but the bellows were made to throw the wheel-work of the mill into action, either to raise or lower the shuttle.

Of late years a new kind of water-wheel governor has been introduced, the principles of which are nearly the same as the governor of a steam-engine. It has a revolving pendulum, which receives its motion from the mill, and in proportion as the machinery moves faster or slower, the centrifugal force acts with greater or less force upon the balls of the governor, making them approach to, or recede from, the perpendicular axis. This raises or depresses an iron cross, which slides upon the perpendicular axis of the revolving pendulum, and by acting on a lever, is made to engage the sluice with a train of wheel-work, which is kept in constant motion by the power of the water-wheel. When this train is connected with the sluice, it operates upon it so as to enlarge or lessen the passage of the water to the water-wheel, and by augmenting or lessening the quantity of water falling on the wheel, increases or diminishes its speed.

This sluice is made on the principle of the throttle-valve of steam-engines. In order that it may be moved by a small power, it is poised on an axis of motion passing through the middle of the sluice. When it is turned edgewise to the stream of water, it makes no obstruction; but if it is turned perpendicularly, it closes the passage of water, or by placing it more or less obliquely, it alters the area of the passage for the water.

The axis on which the sluice turns, if horizontal, should be one-third of the height of the sluice from the bottom, in order that the pressure of the water above the centre may balance that below.

So long as the machinery is moving at a proper velocity, this wheel-work of the sluice apparatus is not connected with the sluice, and it remains at rest. But if the mill goes too slow, the cross is depressed, and striking the lever in an opposite direction, connects the sluice with a different part or train of wheel-work, which has a motion in a contrary direction to the former, and so produces a contrary effect on the sluice.

The train of wheel-work is so calculated, as to reduce the action on the sluice to a very slow motion, and it is found, from experience, that this is necessary. Where the area of the aperture is too suddenly changed, the effect on the water-wheel would be too violent. See a more complete description of this contrivance in Vol. XXIII. *MILL-Work*.

On the Construction of the Wheel-race and Water-course.—The wheel-race should always be built in a substantial manner with masonry, and if the stones are set in Roman cement, it will be much better than common mortar. The earth behind the masonry should be very solid, and if it is not naturally so, it should be very hard rammed and puddled, to prevent percolation of the water. This applies more particularly to breast-wheels, in which the water of the dam or reservoir is usually immediately behind the wall or breast in which the wheel works, a sloping apron of earth being laid from the wall in the dam to prevent the water leaking. The wall of the breast should have pile planking (see *CANAL*) driven beneath, to prevent the water from getting beneath, because that might blow up the foundation of the race. The stones of the race are hewn to a mould, and laid in their places with great care; but afterwards when the side walls are finished, and the axis of the wheel placed in its bearings, a gauge is attached to it and swept round in the curve, and by this the breast is dressed smooth, and hewn to an exact arch of a circle: the side walls in like manner are hewn flat and true at the place where the float-boards are to work. It is usual to make the space between the side walls two inches narrower at each side, in the circular part where the floats act, than in the other parts.

In some old mills the breast is made of wood planking, but this method has so little durability that it cannot be recommended. In modern mills, the breast is lined with a cast-iron plate, but we do not approve of this, because it is next to impossible to prevent some small leakage of water through the masonry, and this water being confined behind the iron breast cannot escape, but its hydrostatic pressure to force up the iron is enormous; and if the water can ever insinuate itself behind, the whole surface of the plate rarely fails to break it, if not to blow it up altogether. This is best guarded against by making deep ribs projecting from the back of the plate, and bedding them with great care in the masonry; these not only strengthen the plate, but also cut off the communication of the water, so that it cannot act upon larger surfaces at once, than the strength and weight of the plate can resist. Stone is undoubtedly the best material for a breast. In overshot-wheels the loss of water, by running out of the buckets as they approach the bottom of the wheel, may be considerably diminished by accurately forming a sweep, or casing round the lower portion of the wheel, so as to prevent the immediate escape of the water, and causing it to act in the manner of a breast-wheel, which has been already described. While this improvement remains in good condition, and the wheel works truly, it produces a very sensible effect; but it is frequently objected to, because a stick or a stone falling into the wheel would be liable to tear off part of its shrouding, and damage the buckets; and again, a hard frost frequently binds all fast, and totally prevents the possibility of working during its continuance;

nuance; but we do not think the latter a great objection, for the water is not more liable to freeze there than in the buckets or on the shuttle, and may be prevented by the same means, *viz.* by keeping the wheel always in motion; a very small stream of water left running all night will be sufficient. Mr. Smeaton always used such sweeps, and with very good effect; it is certainly preferable to any intricate work in the form of the buckets.

On setting out Water-courses and Dams.—The most ancient mills were under-shot-wheels placed in the current of an open river, the building containing the mill being set upon piles in the river. It would soon be observed that the power of the mill would be greatly increased, if all the water of the river was concentrated to the wheel, by making an obstruction across the river which penned up the water to a required height; and also to form a pool or reservoir of water. A sluice or shuttle would then become necessary to regulate the admission of water to the wheel, and other sluices would be necessary to allow the water to escape in times of floods; for though in ordinary times the water would run over the top of the obstruction or dam, yet a very great body of water running over might carry away the whole work, by washing away the earth at the foot of the dam, and then overturning it into the excavation. This is an accident which frequently happens to mills so situated, and the danger is so obvious, that most water-mills are now removed to the side of the river, and a channel is dug from the river to the mill to supply it with water, and another to return the water from the mill to the river. The difference of level between these two channels is the fall of water to work the mill, and this is kept up by means of a weir or dam entirely across the river; but the water can run freely over this dam in case of floods, without at all affecting the mill, because the entrance to the channel of supply is regulated by sluices and side walls.

The dam should be erected across the river at a broad part, where it will pen up the water so as to form a large pond or reservoir, which is called the mill-pond or dam-head. This reservoir is useful to gather the water which comes down the river in the night, and reserve it for the next day's consumption; or for such mills as do not work incessantly, but which require more water, when they do work, than the ordinary stream of the river can supply in the same time. The larger the surface of the pond is, the more efficient it will be; but depth will not compensate for the want of surface, because as the surface sinks, when the water is drawn off, the fall or descent of the water, and consequently the power of the water, diminishes.

The dam for a large river should be constructed with the utmost solidity; wood framing is very commonly used, but masonry is preferable. Great care must be taken, by driving pile planking under the dam, to intercept all leakage of the water beneath the ground under the dam, as that loosens the earth, and destroys the foundation imperceptibly; when a violent flood may overthrow the whole. It is a common practice to place the dam obliquely across the river, with a view of obtaining a greater length of wall for the water to run over, and consequently prevent its rising to so great a height, in order to give vent to the water of a flood. But this is very objectionable, because the current of water constantly running over the dam, always acts upon the shore or bank of the river at one point, and will in time wear it away, if not prevented by expensive works. This difficulty is obviated, by making the dam in two lengths which meet in an angle \triangleright , the vertex pointing up the stream. In this way the currents of water, coming from the two opposite parts of the dam, strike together, and

spend their force upon each other, without injuring any part. A still better form is a segment of a circle, which has the additional advantage of strength, because if the abutments at the banks of the river are firm, the whole dam becomes like the arch of a bridge laid down horizontally. This was the form generally used by Mr. Smeaton.

The foot of the dam where the water runs down should be a regular slope, with a curve, so as to lead the water down regularly; and this part should be evenly paved with stone, or planked, to prevent the water from tearing it up, when it moves with a great velocity.

When the fall is considerable, it may be divided into more than one dam; and if the lower dam is made to pen the water upon the foot of the higher dam, then the water running over the higher dam will strike into the water, and lose its force. There is nothing can so soon exhaust the force of rapid currents of water as to fall into other water, because its mechanical force is expended in changing the figure of the water (see *circular weir* in our article CANAL); but when it falls upon stone or wood, its force is not taken away, but only reflected to some other part of the channel, and may be made to act upon such a great extent of surface as to do no very striking injury at any one time, but by degrees it wears away the banks, and requires constant repairs: for it is demonstrable that, as much of the force of the water as is not carried away by the rapid motion with which it flows, after passing the dam, must be expended either in changing the figure of the water, or in washing away the banks, or in the friction of the water running over the bottom.

The cotton-works of Messrs. Strutt at Belper, in Derbyshire, are on a large scale, and the most complete we have ever seen, in their dams and water-works. The mills are turned by the water of the river Derwent, which is very subject to floods. The great weir is a semicircle, built of very substantial masonry, and provided with a pool of water below it, into which the water falls. On one side of the weir are three sluices, each 20 feet wide, which are drawn up in floods, and allow the water to pass sideways into the same pool; and on the opposite side is another such sluice, 22 feet wide. The water is retained in the lower pool by some obstruction which it experiences in running beneath the arches of a bridge; but the principal fall of the water is broken by falling into the water of the pool, beneath the great semicircular weir.

The water which is drawn off from the mill-dam above the weir passes through three sluices, 20 feet wide each, and is then distributed by different channels to the mills, which are situated at the side of the river, and quite secure from all floods. There are six large water-wheels; one of them, which is 40 feet in breadth, we have mentioned, from the ingenuity of its construction; and another which is made in two breadths, of 15 feet each, we have also described. They are all breast-wheels. The iron-works of Messrs. Walker at Rotherham, in Yorkshire, are very good specimens of water-works; as also the Carron works in Scotland.

The largest works for overshot-mills are in Russia, at Colpino, near St. Petersburg, on the river Neva. They were erected principally under the direction of Mr. Gafcoigne of the Carron works in Scotland, and have been greatly improved by the present director, who is an engineer of his school. An immense dam of granite is built across the river to pen up the water, until it makes a large reservoir. The waste and flood waters do not run over this dam, but are conducted out of the reservoir by a semicircular branch of the river, and run over a great weir to join the original course of the river below the works. The mills

mills are situated in the valley below the great dam, the water being conveyed to the wheels by channels coming through the dam, and conveyed away into a large tail basin, which is the original course of the river. The wheels, which are very numerous, are all 22 feet diameter. They are placed in several different mills, for rolling and forging iron and copper, boring guns, making anchors, &c. These mills are arranged on the sides of the tail basin, which is navigable to bring the boats up to them. There are also two large saw-mills at the end of the semicircular channel.

These works are very complete, owing to the excellent execution of the dam and water-works; but it is not a good plan to place the mills beneath the dam, because if it should fail, or the water pour over it by an extraordinary flood, the mills and buildings below would be in danger of being carried away; whereas, on the other construction, the mills, being placed at a distance from the river, are perfectly safe, and would not be injured if the dam should be wholly carried away. This is not a fault imputable to the gentlemen we have mentioned, as the foundations of these works were commenced in the time of Peter the Great, and too far advanced to admit of altering the plan radically, when the empress Catherine invited Mr. Gafcoigne to Russia, in 1786, to enlarge them to their present magnitude.

On the Distribution of the different Falls of Water in Rivers.—In erecting a mill, care must be taken to place it so that it shall not be impeded by flood-waters, except when they rise to excess. When the water below will not run off freely, but stands penned up in the wheel-race, so that the wheel must work or row in it, the wheel is said to be tailed, or to be in back water or tail water.

Upon most rivers in this country all the falls of water are fully occupied, and at every mill there is a weir, which pens up the water as high as the mill above can suffer it to stand without inconvenience. Each miller is anxious to obtain the greatest possible fall, and he can at any time augment the fall, by raising the surface of his weir; but as this may produce an inconvenience to the mill above, in preventing the water from running freely away from its wheel, it is a constant source of dispute and litigation. A mill may be subjected to tail-water by the concurrence of so many circumstances, that it is frequently very difficult to know where to seek the best remedy, whether the miller ought to raise his wheel higher and diminish his own fall, or insist upon a diminution of his neighbour's below him by lowering his weir.

The following rule is that which Mr. Smeaton constantly followed, in placing successive dams upon rivers, whether for the erection of mills or for navigation. In flat countries, where the falls of water are small, and consequently tail or back water is most troublesome, those dams must be so built, that no one shall pen the water into the wheel-race of the mill next above it, when the river is in its ordinary summer's state. The same rule we have found generally subsisting in ancient mills.

This rule is founded upon reason; for if the erection of a dam does not affect the mill above by tail-water, in dry seasons, when water is the most scarce, it can do no material injury at any other time. Every mill that is well and properly constructed will clear itself of a considerable depth of tail-water, provided it has at the time an increase of the height of water in the mill-dam or head, and an unlimited quantity of water to draw upon the wheel; for if floods produce tail-water, they also increase the head water, and afford a superior quantity to be expended. This is the proper means by which a number of mills on the same river are to be cleared of back-water, as far as is consistent with the mutual enjoy-

ment of their several falls of water. This alone is a very sufficient security against any one being injured. Common breast-mills will bear two feet of tail-water, when there is an increase of head, and plenty of water to be drawn upon the wheel, without prejudice to their performance; but mills well constructed, with slow moving wheels, will bear three and even four feet and upwards of tail-water. Mr. Smeaton mentions having seen an instance of six feet; and it is a common thing in level countries, where tail-water is most annoying, to lay the wheels from six to twelve inches below the water's level of the pond below, in order to increase the fall of water; and, if judiciously applied, is attended with good effect, as it increases the diameter of the wheel, and though it must always work in that depth of tail-water, it will perform full as well, because the water ought always to run off from the bottom of the wheel, in the same direction as the wheel turns.

The law respecting mill property is by no means settled, but is greatly influenced by the custom of the mills upon any river or in any district; some few points however are established. Every one has a right to that fall which the water has, in running through his own grounds, and may make what use he pleases of the descent of the water, provided that he does not divert the water, at the tail of his estate, into any other channel, or that he does not pen up the water higher than the level at which it has always entered into his land; he has also a right to insist that the miller below shall let the water depart from his grounds, at the same level at which it has always been used to do. The knowledge of this is very necessary, because a miller very frequently finds himself seriously injured, when he is not entitled to any redress. It scarcely ever happens that any considerable improvements or alteration in mills can be made, without producing disputes among the parties interested. Suppose, for instance, that there are two ancient mills upon a river, with an unoccupied descent in running over the lands between them, the proprietor of this land, by deepening the channel and erecting a weir, may bring all the fall into one place and erect a mill, without infringing the conditions we have laid down; but still the miller below him may be considerably injured: for in the original state the river, in running down with a regular and easy slope, from the upper mill to the lower, held a great quantity of water, which was a *corps de reserve* for the miller below, and tended to regulate his supply. If the upper mill stopped working, the water contained in the river would still run down to him, and so long as that lasted he could continue to work, perhaps until the upper mill began to work again, and thus he would suffer no interruption. The erection of an intermediate mill cuts off this resource, and he will be obliged to stop working very soon after the new mill stops working; and further, he is obliged to work when the new mill is at work, or else the water poured down will run over his mill-dam and be wasted; but, in the former instance, the water would have come down less suddenly, and he might be able to set to work before the whole of the water had escaped over his weir.

In such a case the lower miller may be inclined to appeal to the law, but he will find that he has no right to prevent his neighbour above from using the water in the same manner as he does himself, and if he finds any alteration in his own mill, it is for want of a capacious mill-pond to reserve the water. In the original state the channel of the river in his neighbour's ground above served him in some measure as a mill-dam, by retaining the water for a given time, though it would not retain it permanently. The advantage of this he had enjoyed for a long time, when it was no inconvenience to his neighbour, but had acquired no right to demand

which will be exerted upon each stone of the masonry to thrust it outwards.

Depth beneath the Surface in Feet.	Pressure on each St. ne, or on every Square Foot, in P. unds.
1	62.5
2	125
3	187.5
4	250
5	312.5
6	375
7	437.5
8	500
9	562.5
10	625

The length and width of the tank does not influence the pressure upon each stone; because, following our first proposition, we are only to regard the magnitude of the plane against which the water acts, and the depth at which it is situated beneath the surface. But in all cases when the plain is not horizontal, the depth of the water will be greater upon some parts of the plane than upon others. The depths must therefore be taken from the *centre of pressure* of the plane; see that article in Vol. VII.

The knowledge of the centre of pressure is required, in order to apply this calculation to wooden vessels, such as the large backs used by brewers; or to find the pressure against the gates of a sluice or lock, or in any other case where the wood planks, or the stones of the masonry are so united together into one mass, that the whole side of the vessel must be removed together. If the plane against which the water acts rises up as high as the surface of the water, and is of a rectangular figure; that is, if all its horizontal dimensions, whether taken at the bottom of the vessel or at the top, are equal, then the centre of pressure is situated at $\frac{2}{3}$ ds of the greatest depth beneath the surface.

Example.—A wooden vat is 18 feet long, and contains water 6 feet deep; required the force which the water exerts against the side of the vat to force it outwards. Two-thirds of 6 feet is 4 feet, which is the depth of the centre of pressure: $4 \times 62.5 = 250$ lbs. is the mean pressure upon each square foot of the plane, 18 feet long \times 6 feet deep = 108 square feet of area \times 250 lbs. 27,000 lbs., which is the force exerted against the side of the vessel, and must be resisted by the strength of the materials.

On the Means of measuring or gauging the Quantity of running Water.—The ancients seem to have had no other measure of running water than that uncertain and fallacious one, which depended wholly on the perpendicular section of a stream, without considering the velocity of the motion. The first who opened a way to the truth was Benedict Castelli, an Italian, and friend of Galileo. He first shewed that the quantity of water, flowing through a given section of a stream, is proportional to the celerity with which the water is carried through that section. This observation engaged philosophers to study the doctrine of the motion of fluids with much diligence, and after Castelli's time there was scarcely any mathematicians who did not endeavour to add something thereto, either by experiments or by reasoning and argument.

But few of them, until the illustrious sir Isaac Newton, had any success, because of the exceeding difficulty of the subject.

Those who studied the theory laid down such theorems as were found to be false, when brought to the test of experiments, and those who laboured in making experiments frequently omitted to observe some minute circumstances, the

importance of which they had not yet perceived. Hence they differed greatly from one another, and almost all of them erred from the real measure.

The theory of hydraulics has never been carried to a very high degree of perfection upon mathematical foundation alone, nor has it hitherto, even with the assistance of experiment, been rendered of much practical utility. Newton began the investigation of the motions of fluids on true principles. Daniel Bernouilli added much valuable matter to Newton's propositions, both from calculation and experiment. D'Alembert, and many later authors, have exercised their analytical talents in inquiries of a similar nature.

Dr. Robison observes that these, and other mathematicians of the first order, seem to have contented themselves with such views as allowed them to entertain themselves with elegant applications of calculus. They rarely had any opportunity of doing more, for want of a knowledge of facts, but they have made excellent use of the few which have been given them.

It requires much labour, great variety of opportunities, and great expence, to learn the multiplicity of things which are combined, even in the simplest cases of water in motion. These advantages seldom fall to the lot of a mathematician, and he is without blame when he enjoys the pleasures within his reach, and cultivates the science of geometry in its most abstracted form. Here he makes a progress which is the boast of human reason, being almost insured from every error, by the intellectual simplicity of his subject. But were we to turn our attention to material objects, we know neither the size and shape of the elementary particles of water, nor the laws which nature has prescribed for their action. We cannot, therefore, presume to foresee their effects, calculate their exertions, or direct their actions, with any reasonable expectations of certainty.

A different and more practical mode of attaining hydraulic knowledge, has been attempted by a distinct class of investigators. These have begun from experiment alone, and have laboriously deduced, from very ample observations of the actual results of various particular cases, the general laws by which the phenomena appear to be regulated, or at least the formulas by which the effect of new combinations may be predicted. But it must be confessed, that these formulas, however accurate, are almost too intricate to be retained in the memory, or to be very easily applied to calculations from particular data.

There are two gentlemen whose labours in this respect deserve very particular notice, professor Michelotti, at Turin, and abbé Bossut, at Paris. The first made a prodigious number of experiments, both on the motion of water through pipes and in open canals. The experiments of Bossut are also of both kinds, and though on a much smaller scale than those of Michelotti, they seem to deserve equal confidence. The chevalier de Buat, who has taken up this matter where the abbé Bossut left it, has prosecuted his experiments with great assiduity and singular success.

Mr. Eytelwein, a gentleman honoured with several employments and titles relative to the public architecture of the Prussian dominions, made a translation of Buat's works into German, with important additions of his own; and he also published "Handbuch der Mechanik und der Hydraulik," Berlin, 1801. In this compendium of mechanics and hydraulics, he has collected the principal facts that have been ascertained, as well by his own experiments as by those of former authors, especially such as are the most capable of practical application. He appears to have done this in so judicious a manner, as to make his book a most valuable abstract

abstract of every thing that can be deduced from theory, respecting natural and artificial hydraulics. The elegant conciseness of his manner deserves so much the more praise, as his countrymen too often make a merit of prolixity.

In our article DISCHARGE, we have given the general principles of the motion of spouting fluids; and under RIVER the theory of water running in rivers. The object of the present article will be to lay down such rules as may be immediately applicable to the use of the engineer.

In all cases of gauging streams, the quantity which flows, in any given time, is obtained by measuring the area of the aperture, or channel, through which the water flows, and finding the velocity with which the water moves through that aperture. To find the area of the aperture is a simple operation of mensuration, but to ascertain the velocity is not so easy. There are two different methods of determining the velocity. The first is, by observing the rate of motion of the surface, either by means of small light bodies thrown into the stream, or by employing instruments adapted to measure the rate at which the stream moves. This method is only applicable in cases of open canals and rivers, where the water flows with a slow motion. The other method is more general, and is applicable to the greatest velocities; because it is derived from calculation, according to the depth of water, or height of column, which urges the flowing water, and occasions its motion.

To measure the Quantity of Water running in a River or Canal. First Method.—Choose a part of the channel where the banks are of a determinate figure, and where they continue of the same breadth and depth for a length of ten, twenty, or thirty feet, the longer the better, and the more regular the banks are, the better the observations will be. Measure the breadth and the depth, or other dimensions which may be necessary, to find the area, or section of the passage, through which the water flows. Take these measures at several different points, and if there is any difference at different places, find the area at each place, and take a mean between them.

Then proceed to find the velocity of the motion, by throwing in a cork, or other light body, and observing, by a stop-watch, or pendulum, what number of seconds it takes to flow through a given length of the channel; for instance, the length of ten, twenty, or fifty feet, which was chosen in the first instance for the experiment, and marked out by stretching two strings, parallel across the river. This trial must be repeated several times, and as the instant when the floating body arrives at the last string, can be very exactly noted, this method admits of considerable exactness. A mean of the different results must be taken for the true velocity.

It is true that this only gives the velocity of the water at the surface, and the water moves with different velocities at different depths, beneath the surface; (instead of a single light body to float upon the surface of the water), we are recommended to employ a cylindrical rod of wood, of a length something less than the depth of the water: this is to be ballasted by a weight at the lower end, so that it will swim just upright in standing water, and with the upper end of the stick about an inch above water. By using this, instead of a single cork, we are supposed to attain the mean velocity of the stream at its different depths, instead of the velocity of the surface.

Instead of a cylinder of wood, three or four apples, strung together by a string, will answer the purpose very well, the lower ones being loaded by putting nails in them till they are rather heavier than water, so that the apples, when put into standing water, will hang in a per-

pendicular line. Gooseberries are very nearly the weight of water, and may be employed singly, to shew its velocity at different depths.

Example.—A canal measured eight feet in width, and four feet in depth, the sides being perpendicular; then the area of the section is thirty-two square feet. It was found, by experiments with three apples, that the current ran through a space of fifteen feet in five seconds, in another experiment six seconds, and in a third four seconds and a half. What is the quantity of water passing through this canal?

The mean of all these is five seconds and one-sixth, during which the water moved fifteen feet. Now as five seconds and one-sixth is to fifteen feet, so is sixty seconds to a hundred and seventy-four feet, which the stream flows in the space of a minute. Then thirty-two square feet (the area), multiplied by 174 feet, gives 5568 cubic feet, which is the quantity of water flowing through the canal every minute.

This is the method recommended by Defaguliers, and if carefully executed, and the trials frequently repeated, is tolerably exact. Several authors have supposed this method might be much improved, by employing some instrument to shew the velocity of the stream by inspection. There are many ingenious inventions for this purpose.

Stream-Measurers.—M. Pitot invented a stream-measurer of a simple construction, to find the velocity of any part of a stream. This instrument is composed of two long tubes of glass open at both ends, and placed in a perpendicular direction in the stream of water: one of these tubes is cylindrical throughout and straight; but the other has its lowest extremity bent nearly at right angles, so as to form a horizontal branch, which gradually enlarges like a funnel, or the mouth of a trumpet; both these tubes are fixed to the side of a triangular prism of wood, with the lengths of the tubes parallel to the length of the prism, and their lower extremities both on the same level; the horizontal branch of the tube is carried through the prism, so that the end of the trumpet-mouth opens in one of the angles of the prism. The upright parts of the tubes stand one beside the other, and are let into grooves in the prism, so as to be tolerably well preserved from accidents. The face of the prism in which these tubes stand, is graduated on the edges close by the sides of them into divisions of inches and lines.

To use this instrument, it is placed perpendicularly in the water in such a manner, that the opening of the trumpet-mouth at the bottom of one of the tubes, shall be completely opposed to the direction of the current, in order that the water may pass freely through the funnel up into the perpendicular tube. Then by observing to what height the water rises in each tube, it will be found to rise higher in the tube with the trumpet-mouth than the other, and the quantity of this difference will be the height due to the velocity of the stream.

It is manifest that the water will rise in the straight cylindrical tube to the same height as the surface of the stream: this is by the hydrostatic pressure. But the water of the current entering by the funnel into the other tube, will be compelled to rise above that surface to some certain height, at which height it will be sustained by the impulse of the moving fluid; that is, the momentum or impulse of the stream will be in equilibrium with the column of water sustained in one tube above the surface of that in the other. In estimating the velocity by means of this instrument, we must have recourse to the following rules: if the height of the column sustained by the stream, or the difference of heights in the two tubes be taken in feet, the velocity of

the stream *per* second in feet will be 6.5 times the square root of the height.

If the height be measured in inches, then the velocity in feet *per* second will be 1.88 times the square root of the height, nearly. It will be easy to put the funnel into the most rapid part of the stream, by moving it about to different places, until the difference of altitude in the two tubes becomes the greatest. In some cases, it will happen that the immersion of the instrument will produce a little eddy in the water, and thus disturb the accuracy of the observation; but keeping the instrument immersed only a few seconds will correct this. The wind also would affect the accuracy of the experiments; it is therefore advisable to make them when there is little or no wind.

By means of this instrument, the velocity of water at various depths in a canal or river may be found with tolerable accuracy, and a mean of the whole drawn. Where great accuracy is not required, the bent tube with the funnel at bottom will alone be sufficient, because the surface of the water will be indicated with tolerable precision, by that part of the prismatic frame for the tube which has been moistened by the immersion.

M. Pitot likewise proposed that a similar instrument should be used instead of a log, to determine the rate at which a ship sails. For this purpose, in the middle of a vessel, or as near as can be to the centre of its oscillations, place two tubes of metal of three or four lines in diameter, one of them being straight, and the other bent at bottom and enlarged into a conical funnel. The lower ends of both are to dip into the water in which the vessel sails, and there will be no evil to apprehend from orifices so minute. Into these metallic tubes, two others are closely fitted at a convenient height for the observations. The water will rise, in the first of these tubes, up to its level on the outside of the ship; and in the second, up to a certain height, which will indicate as above the velocity of the vessel. For the funnel being turned towards the prow of the ship, it will, in consequence of the motion, be affected in like manner, as if it were plunged into the stream of a running water. The actual velocity of the vessel is found by the same rules as that of the current. This method has been re-proposed in this country, without any acknowledgments to M. Pitot. We do not, however, recommend its adoption on board a ship; for, notwithstanding its theoretical ingenuity, it is liable to many sources of error in practice, and would not, it is probable, furnish more accurate measures of a ship's way, than those deduced from the common log.

In the practical use of M. Pitot's instrument, a great difficulty is experienced from the oscillations of the water in the tubes, which it is not easy to prevent, and a mean height of the oscillating water must be taken.

M. Du Buat made trials of the instrument, and found it could not be trusted for any other purposes than to give the ratios of different velocities. He found the instrument was better without the straight tube, and he employed only one tube with its lower end turned horizontally, in the direction of the stream, it was made of tinned plate instead of glass, and sufficiently large to admit a float to shew the height of the water in the tube. Instead of making the end of the tube an open trumpet-mouth, he used to close it by a flat plate, with a small perforation in the centre to admit the water through it, or in some cases several small perforations. In this way, the water will rise in the tube, just the same as if it was open; but the oscillations of the column will be avoided, or greatly diminished.

The hydraulic quadrant has been recommended by several authors, for measuring the velocity of water.

It consists of a small quadrant with a divided arch, and having two threads moving round its centre. One of these is short, and carries a plummet which always hangs in air, and serves to place the quadrant in its true position. The other thread is longer, and carries a weight whose specific gravity is greater than that of water, and which plunges more or less deep in the current as the thread is lengthened. The instrument is held over the water, so that the plummet of the long thread hangs in the water, and the force of the current will remove it from the perpendicular, whilst the angular distance from the other thread, which is a vertical line can be ascertained by the divisions on the arch of the quadrant; the quantity of this deviation from the perpendicular is the measure of the force, and consequently of the velocity of the current. Boffut has shewn, that the force of the current is as the tangent of the angle which one thread makes with the other, and gives directions for using this instrument to try a current at different depths.

Dr. Brewster, in his edition of Ferguson's lectures, recommends a small and light wheel, like an undershot water-wheel, with float-boards on its circumference. It is provided with an apparatus to ascertain and record the number of turns it makes, and is held in the stream, so that the water may act upon the float-boards to turn it round; and from the number of turns it makes in any given time, the velocity of the stream may be computed. He directs the wheel to be made of the lightest materials, and about ten or twelve inches in diameter: it is furnished with fourteen or sixteen float-boards. The centre of the wheel is perforated with a hole, and tapped to receive a delicate screw or wire, which forms the axis upon which it revolves, with as little friction as possible. At each end of the screw or axis, is a handle to hold it by, and to support the wheel; and to one of these handles an index is fixed, pointing to divisions on the circumference of the wheel, which consist of 100 parts. This index shews the aliquot parts of a revolution, whilst the number of threads which the wheel advances on the screw shews the number of whole turns it makes.

To prepare this instrument for use, the wheel must be turned round upon the screw until it arrives quite at one end of it, and till the index points to zero of the divisions on the rim of the wheel; then hold the axis or screw horizontally by the two handles, so that the floats dip in the water and turn the wheel round upon the screw.

By means of a stop-watch, or a pendulum, find how many revolutions of the wheel are performed in a given time, a minute, for instance. Multiply the mean circumference of the wheel, *i. e.* the circumference deduced from the mean radius, measured from the centre of impulsion upon the float-boards to the centre of the wheel, by the number of revolutions, and the product will be the number of feet which the water moves through in the given time. On account of the friction of the screw, the resistance of the air, and the weight of the wheel, its circumference, will move with a velocity a little less than that of the stream; but the diminution arising from these causes, may be estimated with sufficient precision for all the purposes of the practical mechanic.

This, we think, is one of the best stream-measurers, because it will give a correct measure of the motion at the surface of the water; but it will not give the velocities at the different depths beneath the surface, nor do we know any machine which will effectually answer that purpose.

By means of this instrument, we can obtain the velocity of the surface with greater accuracy than perhaps by any other means; but to ascertain the quantity of water which shall

WATER.

shall be discharged, we must know the mean velocity of the water.

Ratio between the mean Velocity of running Water and the Velocity of the Top and Bottom of a Channel.—M. Du Buat states, that the superficial velocity of a stream of water always bears a certain relation to the mean velocity, so that we can derive one from the other by an arithmetical rule.

From a great number of experiments, he discovered the following laws: 1st, That the velocity at the surface in the middle of the stream, (in slow motions,) is to the velocity at the bottom of the stream, in a ratio of considerable inequality. 2d, This ratio diminishes as the velocity increases, and in very great velocities approaches to the ratio of equality. 3d, What was most remarkable, was, that neither the magnitude of the channel, nor its slope, had any influence in changing this proportion, whilst the mean velocity remained the same. Whether the stream ran in a channel with the bottom covered with pebbles, or coarse sand, the proportions between the two velocities was, as nearly as possible, the same as when it ran in a smooth channel. 4th, If the velocity at the surface in the middle of the stream be constant, the velocity at the bottom will be also constant, and will not be affected by the depth of water or magnitude of the stream. In some experiments, the depth was thrice the width, and in others the width was thrice the depth. This changed the proportion of the magnitude of the section, to the magnitude of the rubbing part, but made no change in the ratio between the velocities at the top and bottom.

The place of the mean velocity in the section of the stream could not be discovered with any precision. In moderate velocities, it was not more than one-fourth or one-fifth of the depth distant from the bottom. In very great velocities, it was sensibly higher, but never in the middle of the depth.

In all cases he computed the mean velocity by measuring the quantities of water discharged in a given time. His method of measuring the bottom velocity was simple, and probably just; he threw in a gooseberry, as nearly as possible of the same specific gravity with the water; it was carried along the bottom without touching it. We have already observed, that the ratio between the velocity at the surface in the middle, and the velocity at the bottom, diminished as the mean velocity was increased. This variation he was enabled to express in a very simple manner, so as to be easily remembered, and to enable us to find any one of them from having observed another.

Dr. Robison states, that if we take unity from the square root of the superficial velocity, in the middle of the stream, expressed in inches *per second*, the square of the remainder is the velocity at the bottom; and the mean velocity is the half sum of these two. Thus, if the velocity of the surface in the middle of the stream be twenty-five inches *per second*, its square root is five; from which if we take unity, there remains four. The square of this, or 16, is the velocity

at the bottom, and $\frac{25 + 16}{2}$, or $20\frac{1}{2}$, is the mean velocity.

This is a very curious and most useful piece of information. The velocity of the surface in the middle of the stream, is the easiest measured of all, by any light small body floating down it, or by a stream-measurer; and the mean velocity is the one which regulates the discharge, and all the most important consequences.

Dr. Robison gives the following table of these three velocities, which will save the trouble of calculation in some of the most frequent questions of hydraulics.

Velocity in Inches <i>per Second</i> .			Velocity in Inches <i>per Second</i> .

The knowledge of the velocity at the bottom is of use to an engineer, to enable him to judge of the action of a stream on its bed. Every kind of soil will bear a certain velocity without changing the form of the channel. A greater velocity would enable the water to tear it up, and a smaller velocity would permit the deposition of more movable materials

rials from above. It is not enough, then, for the permanency of a river, that the accelerating forces are so adjusted to the size and figure of its channel, that the current may acquire an uniform velocity, and cease to accelerate. It must also be in equilibrio with the tenacity of the channel.

It appears from observation, that a velocity of three inches *per second* at the bottom, will just begin to work upon fine clay fit for pottery, and however firm and compact it may be, it will tear it up. Yet no beds are more stable than clay, when the velocities do not exceed this, for the water soon takes away the impalpable particles of the superficial clay, leaving the particles of sand sticking by their lower half in the rest of the clay, which they now protect, making a very permanent bottom, if the stream does not bring down gravel or coarse sand, which will rub off this very thin crust, and allow another layer to be worn off. A velocity of six inches *per second*, will lift fine sand; eight inches will lift sand as coarse as linseed; twelve inches will sweep along fine gravel; twenty-four inches will roll along rounded pebbles an inch in diameter; and it requires three feet *per second* at the bottom to sweep along shivered angular stones of the size of an egg.

Dr. Young gives an excellent simple rule for the same object, which is only a trifle different from Dr. Robison's; he states, that from a mean of all the best experiments, he found that, if the square root of the mean velocity of any stream (running in an uniform open channel) be added to such mean velocity, it will give the superficial or top velocity in the middle; or if deducted therefrom, it will leave the bottom velocity: whence we have deduced the following practical rule, *viz.*

1. Having found the top velocity, expressed in any convenient measure, which will correspond with the result required.

To find the bottom velocity, add the constant number .25 (or $\frac{1}{4}$) to the top velocity; extract the square root of the sum, and double it; again add 1 to the top velocity, and from the sum deduct the double root before found: the remainder is the bottom velocity of the stream.

2. To find the mean velocity from the top velocity, add the constant number .5, (or $\frac{1}{2}$) to the top velocity, and from their sum deduct the square root found in the first rule: the remainder is the mean velocity.

Or, 3. To find the mean velocity from the bottom velocity, add the constant number .25, (or $\frac{1}{4}$) to the bottom velocity, and extract the square root of the sum; then to this square root add the bottom velocity, and the constant number, .5, and their sum is the mean velocity.

These are true in all cases, provided the top and bottom velocities are related to each other, as Dr. Young states. For example, Mr. Watt observed the surface of the water in an open canal to move with a velocity of 17 inches *per second*: What was the bottom velocity?

By our first rule $17 + .25 = 17.25$, of which extract the square root; it is 4.15; twice this is 8.3. Again, to the top velocity 17 add 1 = 18, and deduct 8.3, it leaves 9.7 for the bottom velocity. Mr. Watt observed the bottom velocity to be 10 inches *per second*.

2. To find the mean velocity, add .5 to the top velocity 17, it gives 17.5; deduct 4.18, and we get 13.32 inches *per second* for the mean velocity.

3. If we take Mr. Watt's observation of the bottom velocity of 10 inches *per second*, instead of the top; then to find the mean velocity $10 + .25 = 10.25$, of which the square root is 3.201; and $10 + .5 = 10.5$; add these together, thus $(3.201 + 10.5) = 13.701$ inches *per second* for the

mean velocity; which only exceeds that deduced from the top velocity by little more than $\frac{1}{4}$ of an inch in a second.

By the aid of this rule, and the wheel stream-measurer before described, great accuracy may be obtained. Care must be taken to apply the wheel in the centre of the stream, on the surface, or rather at that place where the velocity of the surface is found to be the greatest.

Second Method of measuring the Flowing of Water in an open Canal.—When a river flows with an uniform motion, and is neither accelerated nor retarded by the action of gravitation, it is obvious that the whole weight of the water must be employed in overcoming the friction of the water against the bottom and sides.

The principal part of this friction is as the square of the velocity, and the friction is nearly the same at all depths: for professor Robison found, that the flow of the fluid through a bent tube was not increased by increasing the pressure against the sides, being nearly the same when the bended part of the tube was situated horizontally, as when vertically, the same difference of level being preserved.

The quantity of friction will, however, vary, according to the surface of the fluid which is in contact with the solid, in proportion to the whole quantity of fluid; that is, the friction for any given quantity of water will be, as the surface of the bottom and sides of a river directly, and as the whole quantity of water in the river inversely; thus, supposing the whole quantity of water to be spread on a horizontal surface equal to the bottom and sides of the river, the friction is inversely as the depth at which the river would then stand. This is called the hydraulic mean depth.

If the inclination or slope of the surface of water in a river varies, the descending weight, or the force that urges the particles down the inclined plane, will vary as the height of the fall in a given distance; consequently, the friction, which is equal to the descending weight, must vary as the fall; and the velocity being as the square root of the friction, must also be as the square root of the fall. Supposing the hydraulic mean depth to be increased or diminished, the inclination remaining the same, the friction would be diminished or increased in the same ratio; and, therefore, in order to preserve its equality with the descending weight, the friction must be increased or diminished, by increasing the velocity in the ratio of its square to the hydraulic mean depth; that is, increasing the velocity in the ratio of the square root of the hydraulic mean depth.

Mr. Eytelwein's Rule is, that the velocity of a stream will be in the joint proportion of the square root of the hydraulic mean depth, and the square root of the fall in a given distance; or as a mean proportional between these two quantities.

Taking two English miles for a given length upon a stream, we must find a mean proportional between its hydraulic mean depth and its fall in two miles in inches, and inquire what relation this bears to the velocity in a particular case. We may thence expect to determine it in any other. According to Mr. Eytelwein's formula, this mean proportional is $\frac{1}{4}$ ths of the velocity in a second in inches.

In order to examine the accuracy of this rule, we may take an example, which could not have been known to Mr. Eytelwein. Mr. Watt observed, that in a canal 18 feet wide above, and 7 below, and 4 feet deep, having a fall of 4 inches in a mile, the velocity was 17 inches *per second* at the surface, 14 in the middle, and 10 at the bottom. The mean velocity may be called $13\frac{3}{4}$ inches, in a second. Now to find the hydraulic mean depth, we must divide the area of the

WATER.

the section $\left(\frac{18+7}{2} \times 4\right) = 50$ square feet, by the breadth of the bottom and length of the sloping sides added together; whence we have $\frac{50}{20.6}$, or 29.13 inches: and the fall in two miles being 8 inches, we have $\sqrt{8 \times 29.13} = 15.26$ for the mean proportional; $\frac{1}{4}$ ths of which is 13.9, agreeing nearly with Mr. Watt's observation. Professor Robison has deduced from Buat's elaborate theorems 12.568 inches for the velocity, which is considerably less accurate.

For another example we may take the river Po, which falls one foot in two miles, where its mean depth is 29 feet, and its velocity is observed to be about 55 inches in a second. Our rule gives 58, which is perhaps as near as the degree of accuracy of the data will allow.

On the whole, we have ample reason to be satisfied with the unexpected coincidence of so simple a theorem with observation; and in order to find the velocity of a river from its fall, or the fall from its velocity, we have only to recollect that the velocity in inches *per* second is $\frac{1}{4}$ ths of a mean proportional between the hydraulic mean depth and the fall in two English miles in inches. This is, however, only true of a straight river flowing through an equable channel.

For the slope of the banks of a river or canal, Mr. Eytelwein recommends, that the breadth at the bottom should be $\frac{2}{3}$ ds of the depth, and at the surface $\frac{1}{2}$ ds; the banks will then be in general capable of retaining their form. The area of such a section, is twice the square of the depth, and the hydraulic mean depth $\frac{2}{3}$ ds of the actual depth.

M. Du Buat's Rule.—In our article RIVER, we have given the theorem of M. Du Buat for calculating the motion of water in a river or other regular channel, or through pipes. It has been observed by the late Dr. Robison, that the comparison of the chevalier Du Buat's calculations with his experiments is very satisfactory; that it exhibits a beautiful specimen of the means of expressing the general result of an extensive series of observations in an analytical formula; and that it does honour to the penetration, skill, and address of M. Du Buat, and of M. De St. Honore, who assisted him in the construction of his expressions.

Dr. Young's Rule.—Dr. Young justly remarks, in an excellent paper in the Philosophical Transactions for 1808, that the form of Du Buat's expressions is not so convenient for practice as they might have been rendered; and are liable to great objections, in particular cases: for when the pipe is extremely narrow, or extremely long, they become completely erroneous. Dr. Young has, therefore, substituted for the formulæ of M. Du Buat others of a totally different nature; and he professes to have followed Du Buat only, in his general mode of considering a part of the pressure, or of the height of a given fall, as employed in overcoming the friction of the pipe, through which the water flows out of it; a principle which, if not of his original invention, was certainly first published by him, and reduced into a practicable form. We find Mr. Smeaton used it in constructing his MS. tables. By comparing the experiments which Du Buat has collected, with some of Gerstner's, and some of his own, Dr. Young discovered a formula, which appears to agree fully as well as Du Buat's, with the experiments from which his rules were deduced, and at the same time accords better with Gerstner's experiments; and which formula extends to all the extreme cases with equal accuracy. It seems to represent more simply the actual operation of the forces concerned; and it is direct in its application to practice, without the necessity of any successive approximations.

He began by examining the velocity of the water discharged through pipes of a given diameter, with different

degrees of pressure; and found that the friction could not be represented by any single power of the velocity, although it frequently approached to the proportion of that power of the velocity, of which the exponent is 1.8; but that it appeared to consist of two parts, the one varying simply as the velocity, the other as its square. The proportion of these parts to each other must, however, be considered as different, in pipes of different diameters; the first part being less perceptible in very large pipes, or in rivers, but becoming greater than the second in very minute tubes; while the second also becomes greater, for each given portion of the internal surface of the pipe, as the diameter is diminished.

If, with Dr. Young, we express all the measures in English inches, calling the height employed in overcoming the friction f , the velocity in a second v , the diameter of the pipe d , and its length l ; we may make

$$f = a \frac{l}{d} v^2 + 2c \frac{l}{d} v: \text{ for it is obvious, that the fric-}$$

tion must be directly as the length of the pipe; and since the pressure is proportional to the area of the section, and the surface producing the friction to its circumference or diameter, the relative magnitude of the friction must also be inversely as the diameter, or nearly so, as Du Buat has justly observed.

We shall then find, that a must be .0000001 $\left(413 + \frac{75}{d} - \frac{1440}{d+12.8} - \frac{180}{d+.355}\right)$, and c must be .0000001 $\left(\frac{900dd}{dd+1136} + \frac{1}{\sqrt{d}} \left(1085 + \frac{13.21}{d} + \frac{1.0563}{dd}\right)\right)$.

Hence it is not difficult to calculate the velocity for any given pipe, open canal or river, with any given column of water: for the height required for producing the velocity, including friction, is, according to Du Buat, $\frac{v^2}{510}$;

or rather, as it appears from almost all the experiments which the doctor compared, $\frac{v^2}{586}$; and the whole height b

is, therefore, equal to $f + \frac{v^2}{586}$, or $b = \left(\frac{al}{d} + \frac{1}{586}\right) v^2 + \frac{2cl}{d} v$; and assuming $b = \frac{1}{al \div d + .00171}$, and also

assuming $e = \frac{bcl}{d}$, we have $v^2 + 2cv = bb$; whence, $v = \sqrt{bb + e^2} - e$; which is a general theorem.

In order to adapt this formula to the case of rivers, we must make l (the length) infinite; by which b becomes $\frac{d}{aP}$ and $bb = \frac{d}{a} \times \frac{b}{l} = \frac{ds}{a}$; s being the sine of the inclination of the water's surface, and $d = 4$ times the hydraulic mean depth. The hydraulic mean depth is the area of the section of the moving water, divided by as much of the circumference of that area, as the water touches. And since e is here $= \frac{c}{a} v = \frac{\sqrt{ads + e^2} - c}{a}$; and in most rivers, v becomes nearly $\sqrt{20000ds}$.

Another useful rule by Dr. Young, is to find the superficial velocity of the water in a river by adding to the mean velocity

WATER.

velocity of a river its square root; this gives the velocity at the surface; and by subtracting the same square root, we get the velocity at the bottom.

N. B. $2.618 - \sqrt{2.618} = 1$, and $.382 + \sqrt{.382} = 1$; which it may be useful to remember, with reference to this last rule.

Dr. Young made a comparison of his general theorem, as above, with forty experiments extracted from the collection which served as a basis for Du Buat's calculations; and he found that the mean error of his formula is $\frac{1}{3}$ th of the whole velocity, and that of his own $\frac{1}{7}$ th only. But, omitting the four experiments, in which the superficial velocity only of a river was observed, and in which he calculated the mean velocity by Du Buat's rules, the mean error of the remaining 36 is but $\frac{1}{3}$ th, according to Dr. Young's mode of calculation, and $\frac{1}{7}$ th according to M. Du Buat's; so that, on the whole, the accuracy of the two formulæ may be considered as precisely equal with respect to these experiments.

In the six experiments which Du Buat has wholly rejected, the mean error of his formula is about $\frac{1}{3}$ th, and that of Dr. Young's $\frac{1}{7}$ th. In fifteen of Gerstner's experiments, the mean error of Du Buat's rule is $\frac{1}{4}d$, that of Dr. Young's $\frac{1}{4}$ th; and in the three experiments which Dr. Young made with very fine tubes, the error of his own rules is $\frac{1}{3}$ th of the whole; while in such cases Du Buat's formulæ completely fail.

It would be useless to seek for a much greater degree of accuracy, unless it were probable that the errors of the expe-

riments themselves were less than those of the calculations. But if a sufficient number of extremely accurate and frequently repeated experiments could be obtained, it would be very possible to adapt Dr. Young's formula still more correctly to their results.

In order to facilitate the computation, Dr. Young made tables of the co-efficients a and c for 44 different values of a , both in French and English inches, which may be seen in the Philosophical Transactions for 1808; but instead of inserting them, we shall give a far more extended table, which we have carefully deduced from Dr. Young's formula and table, and put it in a form more directly applicable to practice.

Let d represent four times the hydraulic mean depth of an open canal.

Note.—The hydraulic mean depth is the area of the section through which the water runs, divided by so much of the circumference of that section as is touched by the water.

Note also.—In case of close pipes running a full bore of water, the diameter of the pipe is four times the hydraulic mean depth.

s represents the sine of the inclination of the water's surface; that is, the height of the head or rise, divided by the length or distance of the slope in which such rise takes place.

v , the mean velocity *per second*, in inches.

The other symbols used in the theorem are shewn at the head of the different columns of the Table.

WATER.

Dr. Thomas Young's Theorem, with a new and enlarged Table deduced therefrom, expressly for our Work, for calculating the Velocity of Water flowing in Rivers, Channels, or Pipes.

THEOREM. The mean Velocity *per* Second, in inches or *v*, is = $\sqrt{\left(\frac{d}{a^3} + \frac{c^2}{a^2}\right) - \frac{c}{a}}$

<i>d</i>	$\frac{d}{a}$	$\frac{c^2}{a^2}$	$\frac{c}{a}$	<i>d</i>	$\frac{d}{a}$	$\frac{c^2}{a^2}$	$\frac{v}{a}$

Use of the Table.—To render this theorem useful to those who are not familiar with the use of algebraic expressions, we shall give an example of the manner of calculating a stream of water, all the operations being performed by common arithmetic, with the help of the preceding Table.

1. If it is a stream of water running in an uniform channel, take a sufficient number of dimensions of the transverse section of the channel, and by the rules of mensuration calculate the area of its cross section in square feet. Calculate also, how much of the circumference of such cross section is touched by the water, not including its level top.

Then divide the area in square feet by that portion of the circumference in feet, in order to obtain the hydraulic mean depth; this must be multiplied by 12, to reduce it to inches. Multiply the quotient by 4, and the result is d , the number which is to be sought in the first column of the preceding Table.

If it is a circular pipe of uniform bore, running full of water, its internal diameter, taken in inches, is already equal to four times the hydraulic mean depth, without any computation; and accordingly the diameter of the pipe in inches is to be sought for in column 1.

2. By a spirit-level or otherwise, ascertain the perpendicular fall or difference of level, between any two distant points on the surface of the water, if it is an open stream, and find the distance between these points of levelling, by measuring upon a parallel to the surface of the stream. These may be taken in any convenient measures; but the fall and the distance must be reduced to the same measures; then divide the fall by the distance, and the quotient is s , or a decimal number, which is the sine of the inclination of the stream.

If it be a close pipe, the perpendicular fall must be the difference of level between the surface of the reservoir and the place of discharge; divide this by the length of the pipe.

3. Having found d , in column 1 of the Table, take out the number opposite to it in the second column, entitled $\frac{d}{a}$ (that is, d divided by a), and multiply this tabular number by the decimal number s .

Note.—It will sometimes happen that the exact amount of d is not to be found in column 1, but it will fall between two of the numbers therein; then take out the least of those numbers before d , and find how much is to be added thereto, by the following rule: Take the difference of the two numbers in col. 1. between which d falls; also the difference of the numbers opposite to them in col. 2.; also take the difference between the number d , and the least of the two numbers between which it falls. Now, by the Rule of Three, say, as the whole difference of the two numbers in col. 1. is to the same in col. 2., so is the difference between d and the number above it in col. 1. to a fourth number, which is the proportional part to be added to the number of col. 2. before d .

4. Take out the tabular number from col. 3. which is entitled $\frac{c^2}{a^2}$; (that is, the square of c divided by the square of a).

But here *note*, in case of calculating a proportional part, (as directed in the last rule,) it is not always to be added (as in col. 2.); but sometimes, on the contrary, it is to be subtracted, accordingly as the numbers in that part of col. 3. are increasing or decreasing; and for greater ease of discovering this, a * is placed opposite 14, and between 200 and 300 of col. 1., to shew the places where these changes take place, from decrease to increase, and the contrary.

5. Multiply s , the result of the second operation, and $\frac{d}{a}$, the result of the third operation, together, and to the product add $\frac{c^2}{a^2}$, as found by the fourth operation: then extract the square root of this sum.

6. Take out $\frac{c}{a}$ from col. 4., and apply the proportional part as before, if necessary; deduct this number $\frac{c}{a}$ from the square root last found, and the remainder or result is the mean velocity of the stream in inches per second, which was required.

Should this result be afterwards wanted in feet per minute, the numbers last obtained must be multiplied by 60, and divided by 12; or rather, multiplied at once by 5, which is the same thing.

To obtain the quantity of water discharged in a minute; multiply the area of the section of the stream by the velocity now found; taking care, if the area is in square feet, to express the velocity of the water in feet; or if the area is in square inches, the velocity must be expressed in inches, and the product or result will be in cubic feet or cubic inches, accordingly.

Example 1.—The Academy of Sciences at Paris were occupied, during several months, with an examination of a plan proposed by M. Parcieux, for bringing the water of Yvette into Paris; and, after the most mature consideration, gave in a report of the quantity of water which M. De Parcieux's aqueduct would yield. Their report was afterwards found erroneous in the proportion of at least 2 to 5; for when the waters were brought in, they exceed the report in this proportion. Indeed, long after the giving in the report, M. Perronet, the most celebrated engineer in France, affirmed, that the dimensions proposed were much greater than were necessary; and said that an aqueduct of $5\frac{1}{2}$ feet wide, and $3\frac{1}{2}$ deep, with a slope of 15 inches in a thousand fathoms, would have a velocity of 12 or 13 inches per second, and would bring all the water furnished by the proposed sources. The great diminution of expence occasioned by the alteration, encouraged the community to undertake the work. It was accordingly began, and partly executed. The water was found to run with a velocity of near 19 inches, when it was $3\frac{1}{2}$ feet deep.

M. Perronet founded his computation on his own experience alone, acknowledging that he had no theory to instruct him.

Let us examine this case by our theorem.

First, The area of the section is 3.5 feet deep \times by 5.5 feet wide = 19.25 square feet.—The circumference which the water touches, consists of the two sides of 3.5 feet each, added to 5.5 feet, the bottom = 12.5 feet. The area 19.25 square feet divided by 12.5 feet gives 1.54 feet, for the hydraulic mean depth \times 12 = 18.48 inches; four times this is $d = 73.92$, which we are to seek in the first column of the table; and may take 74.

Secondly, To find s , take the fall 15 inches, or 1.33 feet, and divide it by the distance, 1000 fathoms, or 6000 feet; the result is .00022, for s , or the sine of the inclination.

Take out from the table the numbers corresponding to 74.

d	$\frac{d}{a}$	$\frac{c^2}{a^2}$	$\frac{c}{a}$
74	1875000	4.872	2.207

WATER.

We now have all the necessary quantities for making the calculation thus: multiply $\frac{d}{a} = 1875000$ by $s = .00022$, and we have 416.25. To this add $\frac{c^2}{a^2} = 4.872$, and it makes 421.122, of which extract the square root, and it is 20.52; deduct $\frac{c}{a} = 2.207$ from this, and it leaves 18.313 inches *per second* for the mean velocity of the water.

This agrees pretty well with the observation of 19 inches, and Dr. Robison made very nearly the same result by a different mode of calculation.

The velocity of 18.313 inches *per second* $\times 5$ gives 91.56 feet *per minute*, and again multiplied by 19.25 square feet, (the area of the section,) gives 1761.6 cubic feet of water which flow through this canal every minute.

This example is comparatively easy, because the table affords the numbers required; but in some cases the exact numbers cannot be found in the table, we shall therefore give another example.

Example 2.—Mr. Watt measured a canal in the neighbourhood of Birmingham, which was 18 feet wide at the surface of the water, 7 feet wide at the bottom, and 4 feet deep. The water had a declivity of four inches in a mile;—required the velocity with which the water moved, and the quantity which the canal afforded.

To have a complete knowledge of the section, find the length of each sloping side, thus take the projection of the top width over the bottom width on each side, that is, half the difference between the top and bottom width $(18 - 7) \div 2 = 5.5$ feet; now the square of 5.5 is 30.25, and the square of 4 feet the depth is 16, the sum of the two is $(30.25 + 16 =) 46.25$; and the square root of this is 6.8, the length of each sloping side.

First, To find the area and the hydraulic mean depth.—The mean between the widths of the top and bottom is $(18 + 7) \div 2 = 12.5$ feet $\times 4$ feet deep = 50 square feet for the area of the section. To find the circumference which the water touches, add the two sloping sides, each 6.8 feet, to 7 feet, the width of the bottom, and it makes 20.6 feet.

The area, 50 square feet, divided by 20.6 feet, gives 2.4272 feet = 29.126 inches for the hydraulic mean depth; 4 times this is 116.504, which is d , and must be found in the first column of the table. The nearest which can there be found is 100 inches.

Secondly, The fall is 4 inches in the distance of a mile, = 63360 inches, divide 4 by 63360, and it gives .00006313 for s , the sine of the inclination.

Thirdly, The value of $\frac{d}{a}$, in the second column, opposite to 100 in the first column, is 2501000, to which something must be added for the 16.5 inches. To find this quantity, take the difference between the adjacent numbers in column two, *viz.* 2501000 and 4950000 = 2449000, and; lastly, the difference between 100 and 116.5 = 16.5; then say, as 100 is to 2449000, so is 16.5 to 404085, which number is to be added to 2501000, = 2905085, which is $\frac{d}{a}$ for 116.5.

Fourthly, The value of $\frac{c^2}{a^2}$, in column third opposite to 100, is 5.272, to which add .0043, as found by a rule of VOL. XXXVIII.

proportion similar to the above, and it gives 5.276, which is $\frac{c^2}{a^2}$ for 116.5.

Fifthly, Multiply $s = .00006313$ by 2905085, and it gives 183.395; add $\frac{c^2}{a^2}$, or 5.276, as found by the preceding operation, and it gives 188.671; and the square root of this number is 13.736.

Sixthly, The value of $\frac{c}{a}$, in column fourth, is 2.296 for 100, or for 116.5 it is 2.297; deduct this from 13.736, the result of the last operation, and we have 11.439, which is the velocity of the stream in inches *per second*, and this $\times 5 = 57.195$ feet *per minute*. To find the quantity, multiply the velocity, 57.19 feet *per minute*, by 50 square feet the area, and we shall have 285.97 cubic feet, which quantity will flow every minute through this canal.

The velocity here found is considerably smaller than what was observed by Mr. Watt; he found the velocity at the surface 17 inches *per second*, and at the bottom 10 inches, the mean velocity we have already calculated at 13.32.

Dr. Robison, in the *Encyclopædia Britannica*, gives a calculation of this same case by Du Buat's formula, which we have given in the article RIVER. He makes the velocity 11.85 feet *per second*, which differs so little from our computation, that the two theorems may be considered equally accurate; but both appear, by Mr. Watt's observation, to be rather too small in very small declivities of rivers and canals. This is not surprising when we consider, that the experiments, which are the foundation of both these formulæ, were made on small canals; but for this reason, we may expect they will be more accurate when applied to smaller channels, such as mill-courses, aqueducts, &c.

In taking observations to apply this method of calculation to practice, it must be recollected that it always proceeds on the supposition, that the canal is of a regular width and depth, and of an uniform slope throughout. If this is not the case, the canal must be considered in different portions, and each calculated separately. We think greater accuracy will be attained by measuring and carefully levelling 100 yards in which the width and depth are quite regular, than by taking a mile in length, if there are any irregularities in the dimensions, or in the slope in that distance.

On the other hand, the theorem cannot apply at all, unless the length of the channel is such, that the water in it will arrive at an uniform motion without any acceleration of the motion, as it proceeds down. In short and rapidly inclined channels, the water accelerates in consequence of descending further down the fall; but when the canal is long, the velocity arrives at a certain point, and then the friction prevents any farther acceleration; in this case, the theorem applies. We shall not err sensibly in using this theorem for canals of 30 yards in length, or less, if the fall is small.

Method of gauging the Water running through close Pipes.—Dr. Young's theorem and our table, apply with equal, perhaps greater accuracy, to the case of close pipes than to open canals.

All that is necessary is, to measure the internal diameter of the pipe in inches, the length of the pipe, and the difference of the level between the water in the reservoir and the place at which the water is discharged, and proceed as in the former instance; but to render it more clear we shall give two examples.

Example 1.—The city of Edinburgh is supplied with
P water,

water, from springs at Comifton, which is a considerable distance; this is conveyed by two pipes, the first of which was laid in 1720, under the direction of Defaguliers. Dr. Robison mentions one of them, which is 5 inches diameter, 14,637 feet in length; the reservoir at Comifton is forty-four feet higher than the reservoir on the Castle-Hill, in the town of Edinburgh.

First, to find the sine of the inclination, or s , divide the fall 44 feet by 14,637, and it gives .00301, which is s .

Now take five inches, the diameter of the pipe in col. 1., and opposite to it in col. 2. find $\frac{d}{a} = 159700$, which multiply by .00301, gives 479.1; to this add $\frac{c^2}{a^2} = 2.624$ taken from the third column, and the sum is 481.724.

Extract the square root of this, and it is 21.948, from which deduct $\frac{c}{a}$, or 1.620, taken from col. 4., and the result is 20.328, which is the velocity in inches per second, and this \times by 5 = 101.64 feet per minute.

To find the quantity, find the area of the section of the pipe in square feet, by dividing the square of the diameter 25 by 183.3, and it gives .1364 square feet, and this \times by 101.64 feet velocity, gives 13.86 cubic feet per minute for the discharge from the pipe.

Dr. Robison's calculation of this same case by Du Buat's formula, gives a velocity of 20.08 inches per second.

In Mr. Smeaton's Reports, we find the other pipe stated at four and a half inches bore, and that it yielded 160 Scots pints per minute, each 103.4 cubic inches = 9.58 cubic feet. Mr. Smeaton's own calculation was 159 pints.

Example 2.—Mr. Smeaton states, that this pipe was improved by obtaining an increase of fall, making it 51 feet, and that it then yielded 200 Scots pints = 11.98 cubic feet per minute, the bore being $4\frac{1}{2}$ inches, and the length 14,637 feet as before. Mr. Smeaton's calculation was 173 pints = 10.36 cubic feet per minute. What would it be by Dr. Young's theorem? viz. velocity =

$$\sqrt{\left(\frac{d}{a} \times s + \frac{c^2}{a^2}\right) - \frac{c}{a}}$$

To find s , divide the fall 51 feet by the length 14,637 feet; it gives .003484.

To find $\frac{d}{a}$, answering to 4.5 inches in col. 1., take half the difference between the numbers in the second col. opposite to 4 and 5, and add it to the number answering to 4; thus, $\frac{d}{a}$ for 4 is 131560, and $\frac{d}{a}$ for 5 is 159700, difference 28200, which $\div 2 = 14100$, and this $\times 131500 = 145600$, which is $\frac{d}{a}$ for 4.5. Multiply this 145600 by s , or .003484, and it is = 507.67; to this add $\frac{c^2}{a^2}$.

To find $\frac{c^2}{a^2}$ for 4.5, take half the difference between the numbers in the third column for 4 and 5, which is .869, and subtract it from 4.363, the number answering to 4; the result is 3.494, which is $\frac{c^2}{a^2}$ for 4.5; this added to 507.67 is 511.164.

The square root of that number is 22.609, from which deduct $\frac{c}{a} = 1.854$, and it leaves 20.755, which is the velocity per second in inches.

(Note. $\frac{c}{a}$ is found by subtracting half the difference between the numbers for 4 and 5 in the fourth column, from the number answering to 4.)

20.755 inches per second $\times 5 = 103.775$ feet per minute, for the velocity. The area of the pipe is $4.5 \times 4.5 = 20.25$ circular inches, which \div by 183.3, the circular inches in a square foot, is = .1104 square feet for the area of the pipe. Multiply this by 103.775 feet per minute, and we get 11.46 cubic feet per minute for the discharge, which agrees very nearly with the experiment.

Dr. Brewster, in his Encyclopædia, has calculated this same pipe, except that he states it 300 feet longer; he makes the velocity by Du Buat's theorem 20.385 inches per second, and says that on an average of five years, from 1738 to 1742, its maximum discharge was 11.3 cubic feet per minute; he has also calculated the same case by five different formulæ; thus,

	Scots Pints per Minute.	Cubic Feet per Minute.
The quantity of water actually discharged	200	11.968
Calculated by Eytelwein's formula	189.4	11.333
Calculated by Girard's formula	189.77	11.355
Calculated by Du Buat's formula	188.26	11.265
Calculated by M. Prony's simple formula	188.13	11.257
Calculated by M. Prony's table	192.32	11.502
To which we may add Mr. Smeaton's calculation	180.7	10.813
And by Dr. Young's theorem	173.	10.352
	191.5	11.459

It is satisfactory to find the results of so many different processes agree so nearly, and gives us great confidence in the truth of the principles. There is in this case so little difference amongst theorems that any one may be taken; but we think it needless to enter into farther particulars, as the one which we have given effects all that can be desired, and by the help of the table, is the most ready in the application.

We shall only add Mr. Smeaton's table on the friction of water running through pipes, which we find in his manuscript papers, and which he computed from his own observations alone, without knowing the experiments on which the other theorems are founded. They will give rather less than the theorems, and perhaps may approach more nearly to actual practice, in which pipes are not laid with the same care, to avoid roughness within and sudden bends, as when prepared purposely for experiments; we may consider the theorems as the maximum discharge, and Mr. Smeaton's table as the fair average of practice.

Use of the Table.—Find the velocity of the water per minute in feet and decimals in the first column, or in feet per second in the next column, and on the same line underneath the diameter of the bore in inches, you will find the perpendicular height of a column of water in inches and 10ths, necessary to overcome the friction of that pipe for 100 feet in length, and obtain the given velocity.

WATER.

Mr. Smeaton's TABLE for shewing the Friction of Water in Pipes; the Bore of the Pipe being given, and the Velocity of the Water therein; the Column or Height of Head necessary to overcome the Friction, and produce that Velocity, is shewn by this Table for 100 Feet in Length.

Velocity.		Bore of the Pipes in Inches.										
		$\frac{1}{2}$	$\frac{3}{4}$	1	$1\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{3}{4}$	2	$2\frac{1}{4}$	$2\frac{1}{2}$	3	$3\frac{1}{2}$
In Feet per Minute.	In Feet per Second.	Depths of Water necessary to overcome the Friction of the Water in a Pipe 100 feet long, and produce the Velocities marked in the two first Columns.										
		Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.

		Bore of the Pipes in Inches.										

WATER.

We have searched in Mr. Smeaton's papers for the experiments by which this table was made, and we find an investigation, from the experiments of M. Couplet, as recorded by Belidor, on the flow of water through a large pipe at Versailles. From these he deduced the following rule, to find the height of column in inches, corresponding with the velocities in inches *per* second, through a pipe of any diameter given in inches, and 100 feet long.

$$\frac{48 \times (\text{velocity}) + \text{velocity}^2}{52.66 \times (\text{diameter})} = \text{depth of column};$$

or, still more nearly, taking 47.873 for the constant number instead of 48.

It appears that he found this rule did not agree with his own observations; and, in consequence, he made the following experiments himself with a pipe of $1\frac{1}{4}$ inch bore and 100 feet in length; and we believe he arranged them into the table, by projecting and drawing a curve, at least we find that was his usual method in like cases.

Velocity <i>per</i> Second.	Depth of the Column.	
	By the Table.	By Experiment.
Inches.	Inches.	Inches.
$6\frac{1}{2}$	2.1	2.0
$7\frac{3}{4}$	3.0	2.8
$8\frac{3}{4}$	3.7	3.8
10	4.7	4.8
$11\frac{1}{2}$	6.2	6.2
13.4	7.9	7.8
$15\frac{1}{2}$	10.4	10.7
$18\frac{1}{4}$	14.7	14.5
21	18.3	18.1
$23\frac{3}{4}$	22.7	23.0
27	28.4	27.6
$28\frac{1}{4}$	30.8	30.5
$29\frac{3}{4}$	33.8	34.3
$30\frac{1}{4}$	34.8	35.6
35.5	47.2	47.0
$43\frac{3}{4}$	71.2	71.0

This is useful information, because it shews what part of the table may be depended upon. He assumed, that the depth of the column in pipes of other dimensions, was as the length of the pipe directly, and as the diameters inversely.

The form of this table renders it immediately applicable to a great variety of purposes; for instance, an engine is required to pump water to a height of 60 feet; but the water must pass through 1800 feet of horizontal pipe of 5 inches bore, and with a velocity of 140 feet *per* minute. The table shews, that for every 100 feet of this pipe the friction will be equal to a column of 7.6 inches; multiply this by 18.6, and we find the whole friction will be 141.36 inches, this added to 60 feet makes 71.78 feet for the real column which the pump must overcome.

Rules for measuring the Quantity of Water flowing through Sluices or Apertures.—In this, like the former instances, we must multiply the area of the aperture by the velocity with which the water rushes through it.

Sir Isaac Newton, in his Principia, book ii. theo. 8. prob. 36. has demonstrated, that the velocity of water, flowing through holes in the bottom or side of a vessel, ought to be equal to the velocity which a heavy body would acquire, in falling through a space equal to the distance between the surface of the water and the place where it is discharged.

Hence, at the depth of $16\frac{1}{7}$ feet, a stream of $32\frac{1}{7}$ feet in length, ought to flow out in a second of time. And from the laws of falling bodies, it follows, that as the square root of $16\frac{1}{7}$ is to the velocity of the stream flowing out at that depth, so is the square root of any other depth to the velocity of that depth.

Hence, the velocity of water flowing out of a horizontal aperture, in the bottom of a cistern or reservoir, is as the square root of the height, or the depth of water above the aperture.

That is, the pressure, and consequently the depth, is as the square of the velocity; for the quantity flowing out in any given time is as the velocity, and the force required to produce a velocity in a certain quantity of matter in a given time, is also as that velocity; therefore, the force must be as the square of the velocity.

The proposition is fully confirmed by Bossut's and Michelotti's experiment; the proportional velocities, with a pressure of 1, 4, and 9 feet, being 2722, 5436, and 8135, instead of 2722, 5444, and 8166; very inconsiderable differences.

There is another mode of considering this proposition, which is a very good approximation. Suppose a very thin cylindrical plate of water, like a wafer, situated in the orifice; and suppose a constant succession of such plates to be put in motion, one at every instant, by means of the pressure of the whole cylinder standing upon it; let all the gravitating force of the column be employed in generating the velocity of each small cylindrical plate, (neglecting the motion of the cylinder itself,) this plate would be urged by a force as much greater than its own weight, as the column is higher than itself, and this through a space shorter in the same proportion than the height of the column. But where the forces are inversely as the spaces described, the final velocities are equal: therefore, the velocity of the water flowing out must be equal to that of a heavy body falling from the height of the head of water.

This velocity may be found very nearly by the rule which we have before given in undershot water-wheels, or by extracting the square root of the depth in feet, and multiplying it by 481.2: the product is the velocity *per* minute in feet.

In practice it is more convenient to take the depth in inches, instead of feet; then to obtain the velocity in feet *per* minute.

Extract the square root of the depth in inches, and multiply it by 138.88: the product is the velocity in feet *per* minute.

As this rule is the foundation of all calculations for velocities, when friction is not considered, it is constantly wanted: we shall, therefore, give a table, calculated by Mr. Smeaton from the above rule, shewing the theoretic velocities corresponding with different depths.

WATER.

A TABLE shewing the Velocity in Feet per Minute, or per Second, with which Water should issue from an Aperture at any given Depth beneath the Surface, from $\frac{1}{4}$ Inch to 20 Feet, calculated according to the Theory of falling Bodies.

Depth.	Velocity per Minute.	Diff.	Velocity per Second.	Diff.	Depth.	Velocity per Minute.	Diff.	Velocity per Second.	D ff.	Depth.	Velocity per Minute.	Diff.	Velocity per Second.	Diff.

WATER.

If we were to calculate the expence or discharge for any orifice by this table, we should in every instance find it much greater than nature really gives us.

It must be recollected, that this table is not calculated from experiment, but from the theory of falling bodies, which makes no allowance for the loss of velocity, which arises from the friction of the particles of water against the edges of the aperture, and against the neighbouring particles of water which are not put in motion.

Sir Isaac Newton, in making experiments, found the velocity thus determined to be too great, which in one case he corrected. The friction against the sides of the aperture, and the oblique direction of the particles of water before they reach the aperture, both tend to diminish the velocity of the stream; and if these causes could be removed, especially the latter, the Newtonian theory would be confirmed by experiment, or rather experiment would exactly agree with theory.

For, if we suppose water running into the top of a cylindrical tube, and that there is no attraction or friction between the particles of water and the interior of the tube, the velocity of the water, or of each of the particles at the bottom, would be the same, or equal to that which they would have acquired in falling through the same space without the tube, towards the earth.

Hence, to obtain the true velocity, under different circumstances, we must correct the computed velocity by experiments.

It is stated in some elementary works on hydrostatics, that the velocity of the water at the orifice is only equal to that which a heavy body would acquire by falling through half the height of the fluid above the orifice. This was first maintained by sir Isaac Newton, who found that the diameter of the stream is contracted, after it has quitted the orifice; and at the smallest part, the diameter was to that of the orifice as 21 to 25. The area, therefore, of the one was to the area of the other as 21^2 to 25^2 , which is nearly the ratio of 1 to the square root of 2. By measuring the quantity of water discharged in a given time, and also the area of the vena contracta, sir Isaac found, that the velocity at the vena contracta was that which was due to the whole altitude of the fluid above the orifice. He, therefore, concluded, that since the velocity of the orifice was to that at the vena contracta as 1 to the square root of 2, the velocity in the vena contracta was that which was due to the whole altitude of the fluid; and that the velocity at the orifice must be that which is due to one half that altitude, because the velocities are as the square roots of the heights. From this, sir Isaac stated the actual velocity of flowing water to be $\frac{707}{1000}$, or .707 of the theoretic velocities.

But the real quantity of the reduction varies in different cases, according to the nature of the aperture: hence, it is necessary to consider all different forms of apertures, and make a different allowance for each case. To do this, the circumstances of the aperture must be carefully examined.

A, fig. 8. Plate II. *Water-works*, explains the manner in which the filaments of water may be supposed to move, when a stream flows through an aperture in a thin plate.

B shews the motion, when a tube of about two diameters in length is added to the orifice, and when the water flows through the tube with a full stream. This does not always happen in so short a pipe, and never in one that is shorter; but the water will frequently detach itself from the sides of the pipe, and flow through it with a contracted jet.

C shews the motion, when the pipe projects into the inside of the vessel. In this case, it is difficult to make the tube flow full.

D represents a mouth-piece fitted to the hole, and formed agreeably to that shape which a jet would assume of itself. In this case all contraction is avoided, because the mouth of this pipe may be considered as the real orifice; and nothing now diminishes the discharge but a trifling friction of the sides.

When water issues through a hole in a thin plate, the lateral columns, pressing into the hole from all sides, cause the issuing filaments to converge to the axis of the jet, and contract its dimensions after it has quitted the hole, and at a little distance from the hole; and it is in this place of greatest contraction that the water acquires that velocity which we assume as equal to that acquired by falling from the surface: therefore, that our computed discharge may best agree with observation, it must be calculated on the supposition that the orifice is diminished to the size of this smallest section. But the contraction is subject to variations, of which the reasons are not apparent.

The following are the measures of the contracted vein, as ascertained by different authors; the area of the aperture being 1000, the area of the contracted vein at the smallest will be as follows:

Sir Isaac Newton	-	-	-	707
Poleni	-	-	-	714
Greatest found by Bossut	-	-	-	667
Mean of six experiments by Bossut	-	-	-	664
Lowest found by Bossut	-	-	-	666
Bernouilli	-	-	-	641
Michelotti	-	-	-	641
Du Buat	-	-	-	666
Venturi	-	-	-	636
Eytelwein	-	-	-	642

The measures given by Bossut were taken by a pair of spherical compasses, with which he measured directly the diameter of the contracted vein, which he found to preserve the same diameter for some lines. The altitude of the water in the reservoir which Bossut used was 12 feet 6 inches. He measured the vena contracta also, when the water issued by vertical orifices placed 4 feet 3 inches below the surface of the fluid, and he obtained the very same results. The ratio between the area of the orifice and the area of the vena contracta appears from the above, to be by no means constant. It undergoes perceptible variations, by varying the form and position of the orifice, the thickness of the plate in which the orifice is made, the form of the vessel, and the velocity of the issuing fluid.

The dimensions of the smallest section of the contracted vein are at all times difficult to be ascertained with precision. It is, therefore, much more convenient to compute from the real dimensions of the orifice, and to correct this computed discharge by means of an actual comparison of the computed and effective discharges, in a series of experiments made in situations resembling those cases which most frequently occur in practice.

We have made a collection of experiments by various authors, and from them we have deduced the following rule for the real velocity with which water issues from an aperture in a thin plate.

Rule.—Measure the depth of the centre of the orifice beneath the surface of the water in the reservoir in inches, extract its square root, and multiply it by the constant number 85.87: the product is the velocity in feet *per* minute.

If the velocity, as marked in the preceding table, is multiplied by .618, the same result will be obtained. For the contraction of the stream or vein of water, running out of a simple orifice in a thin plate, reduces the area of its section,

at the distance of about half its diameter from the orifice, from 1 to .665, according to the mean different statements above quoted: hence the diameter is reduced to .815.

The quantity of water discharged is very nearly, but not quite, sufficient to fill this section with the velocity due, or corresponding to the height. For finding accurately the quantity discharged, the area of the orifice must be supposed to be further diminished to .619 on account of friction.

In regard to the accuracy of this rule, we must refer to the following table, which contains the results of 35 experi-

ments, and also the calculation for each. We have been obliged to reject about 12 other experiments, because they would not accord with the theorem; but in nearly all of them, the velocity was greater than the rule, and those which are less we have preserved. This was done, because we suspect that many of the cases were not apertures in thin plates; but in wood planks of considerable thickness, such as sluices, the discharge would then be greater than our rule supposes, and such cases should be classed with another description of aperture.

TABLE of Experiments on the Efflux of Water from Apertures on thin Plates.

Authors.	Depth in Inches of the Centre of the Orifice beneath the Surface.	Velocity of the effluent Water per Minute in Feet.	Velocity calculated, by multiplying the Square Root of the Depth by 85.87.	Description of the Aperture.
Smeaton and Brindley	12.5	307 +	304	1 inch square.

	102.5	866 =	869	
	115.	918 =	920	
	128.	967 =	971	
Michelotti	141.	1014 =	1019	3 inches circular
	148.3	1031 =	1045	
	149.2	1035 -	1049	
Boffut	150.	{ 1047 - } 1050 =	1051	3 inches square.
	150.2	1055 =	1053	
Michelotti	275.1	1438 +	1425	1 inch circular.
	276.4	1414 -	1428	1 inch square.
	277.4	1416 -	1430	3 inches circular.
	277.7	1417 -	1431	3 inches square.
	280.1	1404 -	1437	2 inches circular.
	281.6	1446 +	1441	1 inch circular.

These are the results of the discharge through orifices in a thin plate. If we apply to the orifice the shortest cylindrical pipe, that will cause the stream to adhere every where to its sides, we shall find that its length must be twice its diameter. The discharge through such a tube will be about $\frac{1}{2}$ ths of the full quantity, and the velocity may be found by multiplying the full velocities marked in our first Table by .8125.

The greatest diminution of velocity is produced by in-

serting the pipe so as to project within the inside of the reservoir; probably because of the greater interference of the motions of the particles approaching its orifice in all directions: in this case, the velocity is reduced nearly to half of the full velocity.

It was one great aim of the experiments of Michelotti and Boffut to determine the effects of contraction in different cases. Michelotti, after carefully observing the form and dimensions of the natural jet, made various mouth-pieces resembling

fembling it, till he obtained one which produced the smallest diminution of the computed discharge, or till the discharge computed for the area of its smaller end approached the nearest to the effective discharge. And he at last obtained one, which gave a discharge of 983, when the natural discharge would have been 1000. This piece was formed by the revolution of a trochoid round the axis of the jet, and the dimensions were as follow :

$$\begin{array}{r} \text{Diameter of the outer orifice} = 36 \\ \hline \text{inner orifice} = 46 \\ \text{Length of the axis} = 96 \end{array}$$

Eytelwein states that a conical tube, approaching to the figure of the contraction of the stream, procured a discharge equal to .92 of the full velocity; and when its edges were rounded off, of .98, calculating on its least section.

Venturi has asserted, that the discharge of a cylindrical pipe may be increased by the addition of a conical tube at the end of it nearly in the ratio of 5 to 2. (See his experiments in our article DISCHARGE.) But Mr. Eytelwein finds this assertion somewhat too strong, and observes, that

when the pipe is already very long, scarcely any effect is produced by the addition of such a tube. He made a number of experiments with different pipes, where the standard of comparison was the time of filling a given vessel out of a large reservoir, which was not always kept full, because it was difficult to avoid agitation in replenishing it; but this circumstance was rendered indifferent to the results of the experiments by the application of an ingenious theorem. They prove that a compound conical pipe may increase the discharge to twice and a half as much as through a simple orifice, or to more than half as much more as would fill the whole section with the velocity due to the height; but where a considerable length of pipe intervenes, the additional orifice appears to have little or no effect.

The results of the investigations of Bossut, Michelotti, and Eytelwein, agree in a very satisfactory manner respecting the diminution of the discharge in different cases; and we have arranged them in the following Table, which we recommend to engineers, as affording all the necessary information to calculate the discharge from sluices and orifices.

Description of the Aperture through which the Water flows.	Ratio between the real velocity and the theoretic velocity, or that which is due to the whole Depth, as shown by our first Table.	To find the Velocity of the issuing Water.				To find the Number of Cubic Feet of Water which flow per Minute through each Square Inch of the Area.		
		I.		II.		If the Depth is in Feet extract the Square Root and multiply by	If the Depth is in Inches extract the Square Root and multiply by

For a circular orifice or tube formed correspondent to the contracted stream	.983	7.884	2.276	473.04	136.56	3.285	.9483	
For the whole velocity due to the height according to the theorems for falling bodies	1.000	8.019	2.3148	481.14	138.888	3.349	.9645	

To apply these rules for gauging sluices, the following measures must be taken. 1. The perpendicular depth of the bottom of the aperture beneath the surface of the water. 2. The perpendicular depth of the top of the aperture. 3. The horizontal width of the opening. Then, taking the difference between the two first measures leaves the height of the opening.

Note.—If the aperture is not in a vertical plane, but inclined, as is frequently the case in mill-sluices, then the width of the opening must be measured on the slope; but the depths must always be taken perpendicularly beneath the surface of the water.

To make the calculation, find the mean velocity of the effluent water, by calculating the velocity due to the depth of the top of the aperture, and also for the bottom of the aperture, and take a mean of the two.

Note.—When the height of the aperture is less than one-fourth of the whole depth, then the velocity due to the depth of the centre of the aperture will be very near the truth.

Having found the mean velocity in feet, multiply it by the number of square feet in the area of the aperture, and it will give the quantity discharged, in cubic feet.

Example 1.—A sluice, which is four feet wide, is opened or drawn seven inches, and the depth of water above the centre of the orifice is ten feet. The edges of the sluice are cut sharp, so that the borders of the orifice are like a thin plate. What is the velocity and discharge *per* minute in cubic feet?

The square root of 10 is 3.162, which $\times 297.45$ from the table, gives 940.6 feet *per* minute, for the mean velocity of the water.

The area of the aperture is 4 feet, which $\times 7$ inches, $= 28 \div 12 = 2.333$ square feet, for the area of the aperture; therefore, multiply 940.6 by 2.333, and we have 2194 cubic feet *per* minute, for the quantity discharged.

If the depth had been expressed in inches, it would have been 120. The square root of this is 10.95, and this multiplied by 85.87, gives 940.6 feet *per* minute for the velocity, as before. In like manner, the table gives the proper multipliers for finding the velocity in feet *per* second, if it is required.

If it was only required to obtain the quantity discharged, we may proceed more directly, thus. The depth is 10 feet, and the square root is 3.162, \times by 2.065, the number taken from the last column but one of the table, and we have 6.529 cubic feet, which are discharged *per* minute from every square inch of the aperture. The aperture is 48 inches, this $\times 7 = 336$ square inches, this $\times 6.529 = 2194$ cubic feet discharged as before.

If the depth had been 120 inches, then the square root of that number $= 10.95$, and this $\times .5963$, the number in the last column gives 6.529, as the last.

Another method is, to calculate the theoretic discharge, and then make a proper reduction, by multiplying by the decimal number in the first column. Thus, by our first table of velocities, 120 inches deep $= 1521.8$ feet *per* minute, this \times by 2.333 square feet, the area of the aperture gives 3550 cubic feet *per* minute for the theoretic discharge.

The first column of the present table shews that the real discharge is only .618 of the theoretic discharge; therefore, multiply 3550 cubic feet by .618 $= 2194$ cubic feet for the real discharge, as in all the former cases.

This latter method is very convenient, because we can apply a different correction in different cases, according to discretion, and the table of velocities facilitates the calculation very much.

Example 2.—A flour-mill was worked by the water

which ran through a shuttle four feet wide, the depth to the bottom of the aperture was 22 inches, and the shuttle was drawn up one inch and one-quarter, so that the depth to the top of the aperture was 20.75 inches; what is the expenditure *per* minute?

The full velocity due to 22 }
inches depth is by the table } 651.6 feet *per* minute.

Ditto - - - for 20 $\frac{3}{4}$ } 632.7

2) 1284.3

642.15 mean velocity *per* min.

Note.—As 20.75 is not to be found in the table, take 20 $\frac{1}{2}$ $= 628.8$, and add to it half the difference between 20 $\frac{1}{2}$ and 21, *viz.* 3.9 $= 632.7$ feet *per* minute velocity for 20.75, as above.

The area of the aperture 48 inches, $\times 1.25$ inches $= 60$ square inches, $\div 144 = .4166$ square feet. Multiply this by the velocity $= 642.15$ feet, and it gives 267.5 cubic feet *per* minute discharged according to theory.

To reduce this to the practical discharge, multiply by some of the numbers in the first column of the Table opposite, according to the nature of the aperture. The sluice was in a trough, nearly of its own dimensions; so that the bottom and sides nearly corresponded with the aperture; therefore, take .860, and $\times 267.5$ gives 238 cubic feet *per* minute.

It is very convenient to an engineer to be able to calculate the discharge of water by means of the slide-rule. This he may do by means of the two lines usually marked C and D; C being a line of logarithms, and D a line similarly divided on a scale twice as large. By means of these, the square root of any number can be extracted and multiplied by any number at one operation. To use it, find the multiplier which is to be used, upon the line D, and set the slider so that 10 upon C will correspond with it; then seek for the depth upon C, and opposite to it upon D, the required velocity will be found.

Thus,

Line on the slider marked C, depth in inches, 10

Line on the rule marked D, velocity in feet *per* minute, 85.8

And in like manner for any other multipliers: for instance,

Line on the slider marked C, depth in inches 10

Line on the rule marked D, cubic feet *per* minute }
discharged through a } .596
square inch, }

Mr. Eytelwein observes, from Du Buat, that the discharge through an orifice communicating between two reservoirs, and situated beneath the surface of the water in the lower reservoir, is the same as if the water run into the open air, taking the difference of level between the two surfaces, for the depth of the column; he calculates the discharge when the water has to pass through several orifices in the sides of as many reservoirs open above. In such cases, where the orifices are small, the velocity in each may be considered as generated by the difference of the heights in the two contiguous reservoirs; and the square root of the difference will therefore represent the velocity which must be generated in the several orifices, inversely as their respective areas, so that we may calculate from hence the heights of the different reservoirs when the orifices are given. Mr. Eytelwein also considers the case of a lock, which is filled from a canal of

WATER.

an invariable height, and determines the time required, by comparing it with that of a vessel emptying itself by the pressure of the water that it contains, observing, that the motion is retarded in both cases in a similar manner, and he finds the calculation agree sufficiently well with experiments made on a large scale.

Rules for measuring the Quantity of Water which flows over a Weir, or through an Aperture in the Edge of a Board, the Stream being open at Top.—If we suppose water running in a regular sheet over the edge of a large cistern or reservoir, or through a rectangular aperture made in the perpendicular wall or side of the cistern, but open at top, we may take the area of the aperture, and proceed to find the velocity by calculation.

When this subject has been considered theoretically, it has been assumed, that the surface of the water at the place where it runs through the aperture, is without motion, because it stands at the same level with the stagnant water in the reservoir, and that the velocity of the water at different depths will always be as the square root of the depth; that is, beginning at nothing at the surface, the velocity at different depths will increase by that law.

We can find the velocity at the bottom of the aperture, or at any intermediate depth, by the rules and table we have already given; but what we require is the mean velocity of the whole sheet of water. We could obtain this nearly by calculating the velocities for a great number of different depths, increasing by regular intervals, and taking a mean of the whole; but we can effect the same with exactness, if we take two-thirds of the velocity at the bottom, and consider it as the mean velocity of the whole body of water; or, the velocity due to four-ninths of the depth, will give the same result.

In practice we must make allowance for loss of motion by the friction of the water in passing through the aperture, and also because the water does not fill the aperture to the same level as the stagnant water in the reservoir. The motion of the water extends some distance into the reservoir, and the water will consequently have a sloping surface from that part of the surface where the motion begins; the slope will continually increase as the motion of the water accelerates, so as to form a convex surface, which is a portion of a parabolic curve; hence the surface of the water where it is passing through the aperture will be in rapid motion, instead of being motionless as the theory supposes, and the surface will be much lower than the surface of the stagnant water, so that the aperture will only be half full of water; at least this is the assertion of M. Du Buat. But Dr. Robison states, that he always found the depth of the water in the aperture about .715 of the whole depth from the bottom of the aperture to the level of the water in the reservoir.

M. Du Buat's theorem for the discharge through an open aperture, when reduced to English measures, is this: having given the depth from the level surface of the water to the bottom of the aperture, and also the width of the aperture in inches, to find the discharge in cubic inches *per second*.

Let it be remembered that 11.4491 cubic inches of water, or 11.5, will be discharged in a second, through every inch in width of the aperture, when the bottom of it is exactly one inch beneath the level surface of the reservoir. To obtain the discharge for any other depths, this number must be multiplied by the square root of the cube of the depth in inches, and it will give the cubic inches discharged *per second* through each inch in width of the aperture.

Example.—Suppose the depth of the bottom of the aper-

ture beneath the level surface of the water in the reservoir to be 4 inches. The cube of this is 64, the square root of which is 8; therefore, at that depth each inch in width will discharge $8 \times 11.5 = 92$ cubic inches *per second*; if the width of the aperture was 3 feet, then 92×36 inches = 3312 cubic inches, or 1.917 cubic feet, which $\times 60$ seconds = 11.502 cubic feet *per minute*.

Dr. Robison gives the following table, which is rather greater than from the above theorem, and will be found very exact, when the aperture is made in a plank or board half an inch or an inch thick, and so situated that the sides and bottom of the reservoir do not correspond with the edge of the aperture, to lead the particles of water in a current to the aperture.

Depth from the Bottom of the Aperture to the level Surface of the Water, in Inches.	Cubic Feet discharged <i>per Minute</i> through each Inch of the Width of the Aperture.	
	In small Apertures of less than 18 Inches wide.	In larger Apertures than 18 Inches.
1	0.403124	0.428
2	1.140	1.211
3	2.095	2.226
4	3.225	3.427
5	4.507	4.789
6	5.925	6.295
7	7.466	7.933
8	9.122	9.692
9	10.884	11.564
10	12.748	13.535
11	14.707	15.632
12	16.758	17.805
13	18.895	20.076
14	21.117	22.437
15	23.419	24.883
16	25.800	27.413
17	28.258	30.024
18	30.786	32.710

In taking the depth, if it does not exceed four inches, it will not be exact enough to take proportional parts for the fractions of an inch. The following method is exact: if there be odd quarters of an inch, look in the table for as many inches as the depth contains quarters, and take the eighth part of the answer. Thus, for $3\frac{3}{4}$ inches take the eighth part of 23.419, which corresponds to 15 inches. This is 2.927.

If the aperture is not in the side of a large reservoir, but in a running stream, we must augment the discharge, by multiplying the section by the velocity of the stream. But this correction can seldom occur in practice, because in this case the discharge is previously known.

The amount of the allowance for friction and loss of motion must be different in different cases, according to the kind of aperture, or board over which the water flows; but will always be very nearly the same as the allowance, for loss in an aperture or orifice of similar nature. For instance, if the edges of the aperture through which the water runs be a thin plate, then we may find the velocity in feet *per minute* due to the whole depth from the bottom of the notch to the level surface of the water in the reservoir; multiply the square root of the depth in inches by 85.87, as we have

WATER.

have before directed, and take two-thirds of the product for the mean velocity; this multiplied by the number of square feet in the area of the section of the aperture, will give the cubic quantity of water which flows *per* minute in cubic feet. Note, in taking the area of the section, we must measure the whole depth from the level surface, and multiply it by the horizontal width of the aperture, and not simply the section of the water. This is because, the theory upon which the rule is founded supposes the water in the aperture to have no velocity at the surface, and to be upon the level of the standing water. Neither of these suppositions is true in reality, but the result is very nearly true, because the section of the moving water is diminished in proportion to the ve-

locity which the water has at the surface, and in consequence the errors of the two assumptions always correct each other.

We have therefore only to apply a correct theorem to obtain the velocity due to the whole depth, according to the nature of the aperture, and take two-thirds of the product. All the necessary information for this purpose may be taken from the table of multipliers last given, for the velocity of the discharge through apertures; or otherwise, if we take the velocity at the bottom, and multiply it by the depth, and take two-thirds of the product, we shall have the mean velocity. But to make the subject clear we shall give another table for this object.

Rules for obtaining the Velocities and Quantities of Water discharged through rectangular Apertures, which are open at Top.

Description of the Aperture.	To find the mean Velocity of the Water running through the Aperture in Feet <i>per</i> Minute.	To find the Number of Cubic Feet discharged <i>per</i> Minute through each Inch in Width of the Aperture.
<i>Note.</i> —The depths are supposed to be measured from the level surface of the water to the bottom of the aperture, in inches.	<i>Rule.</i> —Multiply the Square Root of the Depth in Inches, by some one of the following Numbers, according to the Case.	<i>Rule.</i> —Multiply the Square Root of the Cube of the Depth in Inches, by some One of the following Numbers, according to the Case.
For a small aperture in one side of a large reservoir, the bottom and sides of which do not correspond with the aperture, so as to lead the particles of water thereto in a stream; the edges of the aperture against which the water runs is supposed to be sharp and made of thin plate; the aperture not to exceed 18 inches long and nine inches deep	57.246	.39754
For an aperture under the same circumstances as the former, but made in a plank with edges from half to one inch thick	58.0493	.40312
For an aperture of great breadth and more than nine inches deep, such as the weir or dam in a river; it is supposed that the water runs over the edge of a plank or waste board, one or two inches thick	58.88	.40886
For an aperture of which the bottom is on a level with the bottom of the reservoir, or for a weir which occupies the whole breadth of a river, and where the water flows over the top of a broad stone-wall so sloped as to conduct the water to the passage	88.92	.6174
For the full discharge according to theory, supposing no loss from friction. Very large and deep weirs will come near to this	92.592	.6430

When the aperture occupies nearly or the whole width of the reservoir, there is no level surface of the water above the aperture, because the water is continually running towards the aperture in a stream; such is the case of a weir across a river, or when water spouts out of the open end of a rectangular trough.

It is extremely difficult to measure the exact height of the water above the bottom of the aperture, for the curvature of the surface of the water will begin several feet up the stream before it arrives at the aperture; and there must be something arbitrary in the measurement, because the surface of the water, even where there is no curvature, is not horizontal but sloping, when the water is in motion. In such cases, the depth must be taken beneath the inclined surface of the water, if we suppose the same prolonged until it reaches the aperture, which can easily be done, by stretching

a line along the surface of the water so as to correspond therewith, at the part above where the curvature commences.

We must also make some addition to the discharge, on account of the motion which the water possesses before it comes to the aperture; to do this with accuracy, we may measure the regular velocity of the stream, by throwing in floating bodies, and observing the distance they pass through in a given time, taking care that we make this observation at a part of the channel, where the surface is in a regular motion and not in a state of acceleration, because what we want is the velocity of the water at that point where the curvature begins, in consequence of the descent through the aperture. Now when the channel is not of an uniform breadth and depth, as in a mill-dam for instance, the velocity of every part of the stream is different, we shall then find difficulty in measuring

WATER.

measuring the velocity by floating bodies, and must apply the wheel stream-measure before described; this will give the precise velocity of the surface at any given spot, and we should choose that place where the curvature begins. The velocity so obtained we must add to the mean velocity, and find the discharge by multiplying the sum by the area of the aperture.

Example.—Suppose the depth of the bottom of the aperture to be eight inches beneath the line of the surface of the water; that the width of the aperture is four feet, and that the aperture is in a thin plate with sharp edges. Also that the stream is found by the wheel to move with a velocity of thirty feet per minute, at the place where the surface of water begins to deviate from its regular slope, and to assume a curvature.

Then take the numbers 57.246 from the first case in our last table, and multiply it by 2.83, which is the square root of eight (the depth); thus $57.246 \times 2.83 = 162$ feet per minute, for the mean velocity of the water; to this add 30 feet for the previous motion = 192 feet per minute. The area of the aperture is 8 inches, or .66 feet \times 4 feet = 2.66 square feet. Multiply 192 feet velocity by 2.66, and we have 510.72 cubic feet per minute, for the quantity discharged.

Water-Gauge for measuring the Quantity of Water afforded by any Spring or Brook.—The most accurate and convenient method for this purpose, is to construct a temporary bank or dam to intercept the stream, and pen it up into a pond, then in the bank or dam fix a board with an aperture in it for the water to flow through. By measuring the width and depth of the aperture as before explained, the quantity can be calculated by the rules already given.

This is what Mr. Smeaton called the water-gauge, and is of most important use, to ascertain the quantity of water which can be procured to supply a canal, or for a town, or a mill, or any other purpose: it is the necessary prelude for undertaking any such kind of work, and all persons employed in such pursuits, should understand the manner of fixing up a gauge, and making the necessary observations.

The dam must be of such a height as to pen up the water into a tolerable large pond compared with the aperture, so that the surface of water shall have no sensible inclination or run towards the aperture; and to avoid this, the larger the pond is the better. The water must have so much fall down from the aperture, as to flow away in a clear stream perfectly free from all obstruction of the water below; but it should not spout out so as to fall far in the air.

The aperture should be a rectangular notch cut in the edge of a broad plank; it will be best to make the length of the notch some even number of inches, as 6, 8, 12, or 24, and the depth correspondent to the quantity expected to flow through the aperture.

We recommend that the edges of the aperture be cut sharp, or even faced with a slip of metal plate, and then our first rule in the last table will apply with great accuracy. The more common practice is, to use a plank of one inch thick, and leave the edges of the aperture of that thickness, only rounding off the sharp angles: in this case, the second theorem in our table must be used; but this is less certain, because the loss of motion from resistance will not bear a constant portion in different depths, for the thickness of the plank is a constant quantity, and therefore bears a different proportion to the quantity discharged, in every case of a different depth.

The accuracy of our rules, when applied to water-gauges, will appear from the following table.

Results of Thirteen Experiments on the Discharge of Water through an Aperture open at Top, made by Messrs. Smeaton and Brindley, and M. Du Buat.

Depth, in Inches, from the level Surface to the Bottom of the Notch, Inches.	Cubic Feet discharged per Minute, ascertained by Observation,		Cubic Feet discharged per Minute by each Inch in Width, as ascertained by Calculation,	
	the Notch being six Inches wide.	by each Inch in Width.	by the Number .403124.	by the Number .39754.
1.	2.75	.4583	.403	.397
1.25	3.68	.613	.56	.554
1.375	4.07	.678	.646	.64
1.625	5.1	.85	.83	.825
* 1.778	5.75	.958	.958	.94
2.312	8.63	1.438	1.42	1.40
3.125	12.9	2.15	2.22	2.2
* 3.2	13.9	2.316	2.3	2.26
* 4.665	24.4	4.066	4.05	4.90
5.	26.1	4.35	4.5	4.45
5.625	28.5	4.75	5.35	5.30
6.5	40.	6.66	6.7	6.57
* 6.753	42.6	7.083	7.06	7.

The two last columns of the table are deduced from calculation, and agree so well with the observations as to give every confidence in the rules. The last column is calculated on the supposition that the aperture is made in a thin plate; but the last column but one is according to Dr. Robison's number, and agrees more nearly with the truth. We believe that Mr. Smeaton's experiments were made on an aperture in a board one inch thick; the aperture was six inches wide. M. Du Buat's four experiments, denoted by * in the table, were in an aperture $18\frac{1}{2}$ inches wide, which we have reduced to six inches, in order to compare them with Mr. Smeaton's. In making this comparison, we have not rejected any experiment, as we were obliged to do in the case of discharge through the apertures beneath the surface.

Self-registering Water-Gauge.—When the produce of a spring or stream is required with great accuracy, the depth of the water flowing through the gauge must be taken very frequently during a whole season, and a mean of all the results obtained. This would require the constant attendance of an intelligent person, and would be liable to mistakes; but a small machine may be made to shew the depth by inspection, so that any careful person can keep the account. Thus, at the side of the water-gauge, fix up a wooden or tin cylinder or trunk, which is open at the bottom, so that the water can enter freely. In this trunk, or tube, let a float be placed, having a small light rod attached to the float that will rise up from it, and appear above the top of the trunk; this part must be divided into inches and tenths, and must have some index fixed to the trunk to read the divisions by. This apparatus must be carefully adjusted; in the first instance, by the person who fixes the gauge, so that its divisions will correspond with the depth of water measured very exactly in the way we have directed; then the float will ever after rise and fall with the surface of the water, and will shew the depth without any necessity of referring to the original mode of measurement, unless it be to verify the adjustment. It is obvious that such an apparatus must be fixed so, that it cannot be deranged either by design or accident. The tube

in which the float acts should be in the still water some feet above the plank in which the aperture is made, and have a proper box, or cover, which can be locked up, to secure the whole. The float should be a hollow copper ball, or a glass bottle, because wood or cork floats absorb the water, and sink deeper therein; and the rod of wood should be well painted.

A still more perfect water-gauge is obtained by a small machine to keep the register; for this purpose, let an eight-day clock of the ordinary construction be fixed up in a kind of centry-box, or small house, over the gauge; this is to be connected by wheel-work, with a cylindrical barrel, which is to be placed in a perpendicular direction, and made to turn round once in a week by the clock; a sheet of paper is wrapped round the barrel, and fastened upon it in the same manner as paper is fastened on a drawing-board.

The perpendicular stem of the float must have a small pencil attached to it, with a slight spring to cause it to bear against the paper on the circumference of the cylinder, so as to mark upon it: in this way the pencil marks, at a different part of the length of the cylinder whenever the float rises or falls, and the cylinder turning regularly on its axis by means of the clock, causes these risings and fallings to be marked on different parts of the sheet of paper, so that when it is removed from the cylinder it will have a curved line traced upon it, which shews all the increments and decrements of rise and fall, and affords an exact register of the flow of water, which may be reduced to cubic measure, by our rules already given.

A different kind of water-gauge has been proposed by M. De Baader: two large casks or other vessels are to be fixed side by side, in such position, that the stream of water may be poured into either of them by a spout or trough. The spout is so contrived, as to turn the stream into one or other of the vessels at pleasure, with the greatest ease, but the stream cannot run into both at once. In each vessel is a large float which is connected with a perpendicular stem, so that the stem rises or falls with the float, as the vessels fill or empty; also at the bottom of each vessel is a valve, or sluice, to allow the water to run out from it, and the perpendicular stem from the float is provided with means to open this sluice, whenever the vessel is full of water, and the float rises to the top, or to shut the sluice whenever the vessel is empty; and the same action turns the stream of supply from the vessel which is full, into that which is empty. In this way, the two vessels act alternately to receive the water, and measure it, for while the spout runs into one vessel its float rises until the vessel is quite full; the float then turns the spout and stream into the other vessel, which we suppose to be already empty, and at the same moment it will open the valve in the bottom of the full vessel; the water then begins to run out of the full vessel and to fill the other, which becoming full in turn, its float opens the valve in its bottom. In this way the machine continues to measure the water, and is provided with a small counting machine to register the number of reciprocations it has made.

We have now, as far as our limits will allow, given all the most useful and practical rules for measuring flowing water; and shall conclude by observing, that this is one of the most intricate and difficult subjects in hydraulics, and that no engineer can be fully competent to direct the execution of large works without studying the subject much farther than we have been able to enter into it. Many untried cases, and combinations of cases, will continually arise, which cannot be decided by any previous knowledge. As a resource for such occasions, we should be well versed in the theory of the subject, so as to modify the rules laid down for simple cases, and adapt them to his particular case, as far as theory can assist him.

If he only pursues the rules laid down by others, without any knowledge of theory, and without entering into the reason and origin of the rules, his experience will not be of much avail, because he will be unable to correct and improve the rules by his own observations, or if he attempts to do so, he may completely spoil them, by making them false in many cases, in order to obtain truth in some one case.

To attain the knowledge to which we allude, the following authors may be consulted.

Julius Frontinus, *De Aquæductibus urbis Romæ Commentarius*; written about the year 100, in the time of the emperors Nerva and Trajan. This contains all the knowledge of the ancients on this subject. It is printed in *Grævii Thesaurus Antiquitatum Romanorum*, vol. iv. 1630 and 1780. A new edition was also published.

Castelli, a disciple of Galileo, *Della Mefura dell' acque correnti*, 1628.

Toricelli *De Motu Gravium Naturaliter Accelerato*, 1643. In this work we find the origin of the proposition, that the velocities of issuing fluids are as the square roots of the depths.

Raphel Fabrettus de Aquis et Aqueductibus veteris Romæ, 1679.

Marriotte, *Traite du Mouvements des eaux*, 1686. This work contains a great number of experiments on the motion of fluids, and particularly on jets of spouting fluids; but the reasoning is frequently erroneous.

Guglielmini, *La Mefura dell' acque correnti*.—Alfo, *Della Natura dell Fuimi*, Bologna. 1697.

Guglielmini de Fluvii et Castellis Aquarum. These contain a theory which has long since been exploded. He first attempted to apply the principles of falling bodies to the motion of waters in open canals and rivers.

Polenus, *De Motu aquæ Mixto*, Patav. 1697, 1718, 1723. Parent Mem. Acad. Par. 1700.

Newton's *Principia*, 1687. This work contains the doctrine, that the velocity of a spouting fluid is equal to that which a heavy body acquires in falling through half the depth of the column; but which is not correct. And in the second edition, 1713, Newton first points out the contracted vein, and the proportion of its area to that of the orifice to be, as .707 to 1.

Polenus *De Castellis per quæ derivantur fluviorum aquæ*, Padua, 1718. He states the area of the contracted vein to be .571 of the area of the orifice, and he discovered, that more water is yielded by a cylindrical pipe than by a simple orifice.

Michelotti, *De Separatione Fluidorum in Corpore Animale*, 1719.

Raccolta De Autori che Trattano dell Moto dell' acque, 3 tom. 4to. Florence, 1723. This most valuable collection contains the writings of Archimedes, Albizi, Galileo, Castelli, Michelini, Borelli, Montanari, Viviani, Cassini, Guglielmini, Grandi, Manfredi, Picard, and Narducci; and an account of the numberless works which have been carried on, in the imbankment of the river Po in Italy.

M. Couplet, *Des Recherches sur le Mouvement des eaux dans les tuyaux de conduit*. *Memoires de l'Acad.* 1732. This is on the motion of water in pipes, and is given by Belidor in his *Arch. Hydraulique*.

Architecture Hydraulique ou l'Art de Conduire d'elever et de ménager les eaux pour les differens besoins de la vie, in 4 vols. 4to. par M. Belidor, *Commissaire Provincial d'Artillerie*, Paris, 1739.

from Comifton and Swanfton, in leaden and iron pipes; but the fupply is very inadequate to the fize of the city.

When water is to be conveyed in an open canal, like the New River, the manner of fetting out and executing the work is fo nearly the fame as for a navigable canal, that it is unneceffary to fay more than we have already given in our article CANAL, except the rules for calculating the neceffary flope or defcent to produce the required velocity of the water; and the beft theorem for this purpofe we have already given in the preceding part of the prefent article.

We fhall only add a few particulars of fome of the largeft modern aqueducts for conveying water.

Aqueduës.—Belidor fates, in his *Architecture Hydraulique*, that one of the fineft fubterraneous aqueducts in France is that of Arcueil, which conducts the water from many collecting channels in a ftone channel. It is fituated in the countries of Rungis, Paret, and Coutin. This aqueduct is 14,920 yards in length, and is conftituted in free-ftone; it extends from the valley d'Arcueil to an elevated water-ciftern, or chateau d'eau, which is at the Porte St. Jaques. The channel has an inclination of 6 inches in 400 yards, or 1 in 2400.

On each fide of the water-courfe is a raifed foot-path 19 inches wide, upon which a perfon can walk as far as the village d'Arcueil. The height of the paffage from the bottom of the water-trough to the under fide of the arch is 6½ feet, except in fome places where they have been obliged to make them lefs, in confequence of the high roads beneath which it paffes.

Another fubterraneous aqueduct of this kind is that of Rocquancourt, which conveys water to Verfailles; it is 3623 yards in length, and in all the length has an inclination of only 3½ feet, which was the utmoft that could be given it. To conftitute this aqueduct, they were obliged in many places to dig to a depth of 30 yards, which rendered the execution of it very difficult. One hundred and fifty shafts were made in the length of this aqueduct. They were not made at equal diftances, but only in fuch places as would facilitate the conveyance of materials; eighty of them were lined with ftone, and the other feventy, which were not required to laft longer than during the conftituteion, were only lined with wood, and ftopped up afterwards with a dome of mafonry, and filled up with earth to the level of the furface.

This aqueduct coft 325,000 livres. From 1675 to 1678 it never yielded more than 6 poudes of water, and fome times gave only 5, 4, 3, or even 2 poudes, according as the dry feafons were of greater or lefs duration. The pouce de fontainier is a meafure of running water ufed by French engineers, which amounts to about .48 Englifh cubic feet per minute; hence the 6 poudes would be 2.88 cubic feet per minute.

A pond was made in 1685 at the head of this aqueduct, to drain a country called Trou d'Enfer; and fince then it has given 10 and 12 poudes, *i. e.* 4.8 and 5.76 cubic feet per minute.

When water is conducted in an open channel, it frequently becomes neceffary to crofs deep valleys; in this cafe, the channel muft be fupported on arches like a bridge. This was the object of thofe vaft Roman aqueducts, of which we find the remains at Nimes, Arles, Frejus, &c. The greateft modern works of this kind are thofe conftituted in the time of Louis XIV. to conduct water to Verfailles and Marly. One of thefe is the aqueduct of Maintenon, for conveying the river Bure to Verfailles: it confifts of three courfes of arches, raifed one above the other, to fupport the water-

courfe, which is a channel of ftone, and on each fide of it is a narrow path with a parapet, which renders it fafe to walk along the fide of the aqueduct when it requires cleaning or repairing.

In the *Philofophical Tranfactions*, it is ftated that this aqueduct is 2560 fathoms in length, and confifts of 242 arches; the fpan of each is 6½ fathoms, and the thicknefs of each pillar to fustain the arches 4 fathoms. On the fide of the valley next to Maintenon, there are thirty-three fingle arches, afterwards feventy-one double ones, (that is, having one arch upon another,) then forty-fix treble ones; at this part the water-courfe is generally 216 feet 6 inches high from the ground up to the floor of the water channel; afterwards there are feventy-two double arches, then twenty fingle ones, which laft reach to a mound of earth, which is raifed 50 feet high above the ground for a great diftance.

The general height from the ground up to the fecond arcade or row of arches is 16 fathoms; from the fecond row to the third or upper arcade 14 fathoms; in the upper arcade, the arches are double the number of thofe they ftand upon; above this is 6 fathoms 6 inches more to the floor of the channel, which is at leaft 7 feet high befides the parapet.

The pillars at the ground are 8 fathoms thick, but with the flopes and fhortenings, which are made in every ftory; the top where the channel runs is reduced to 20 feet broad. There is likewife at each pillar a buttrefs projecting one fathom, and two fathoms wide to ftrengthen the pillars.

There is another great aqueduct raifed on arches in the Plaine de Bue, which conducts water to Verfailles from the Plaine de Scale. This is built with two ranks of arches, and the lower ones are fo much wider than the upper, as to afford room for a carriage-way acrofs the valley about half as high up as the water-courfe. Drawings of thefe great works are given by Belidor.

It is difficult to determine the exact flope which fhould be given to a water-courfe, in order to conduct a given quantity of water; it can only be known by calculation according to the rules we have already given, and which are founded upon experience. Vitruvius recommended a flope of 1 foot fall in 200 feet in length; but Belidor fays this is much more than is neceffary, and that 1 foot fall in 3600 feet of length is quite fufficient, when the channel is ftraight without elbows, or fudden angles, or if the bends at fuch angles are by eafy curves, fo that the water is not retarded in changing its direction. He remarks, that the canal from the pool of Trappes, made by M. Picard to conduct the water to Verfailles, had 9 inches flope in 1000 fathoms, or 1 foot fall in 7998 feet long. When the water was run into this, it took four hours to run 8526 yards, though it was urged by a prefure of 38.3 inches. Alfo that the aqueduct of Rocquancourt before mentioned has only 3 peds fall in all its length, which is 1700 toifes, that is, 1 foot fall in 3400 feet of length. Whence Belidor directs as a general rule to make the fall 1 inch in 100 yards, that is, 1 foot in 3600 feet, provided the bottom of the trough is of fmooth ftone, and not muddy. This is the leaft which can be allowed, and more may be given when the relative levels between the two places will admit of a more rapid defcent.

On the Conveyance of Water in Pipes.—This is an object of great importance. The ancients conducted water in pipes only down hill; but never carried it up again, not knowing that water would rife to its own level; but we can conduct water to very great diftances, and bring it from one mountain to another in pipes, which defcend into the intermediate valleys and rife again, provided that the fpring or place from which

WATER.

which the water comes is somewhat higher than the other end where the water is to be delivered. The water would indeed shew itself at the same level at one end of the pipe as at the other, but it would not run out; and in all cases with the same size pipe, the quantity of water given will increase in proportion as the receptacle at the discharge is below the spring at the other end of the pipe. Hence, if there is a great deal of water to be conveyed to a place situated but little lower than the level of the original spring, a very large pipe must be used to convey any given quantity. But the same quantity may be conveyed in a smaller pipe, and consequently at less expence, if the reservoir is much below the original level.

If the distance is great, the length of the pipes will considerably diminish the quantity of water brought through them, in consequence of the friction of the water against the sides of the pipes; this cannot be prevented, and we must make the bore of the pipe larger, in proportion to the length, if the water be in such quantity and so much wanted as to make it worth the expence. The rules for calculating the proper size of pipes we have already given.

Defaguliers mentions an experiment which he made upon a leaden pipe, whose inward diameter was $1\frac{3}{8}$ inch, and found that at 1400 yards distance from the spring of water that supplied it, it did not give a tenth part of the water that it would have given at thirty yards from the spring, though both places were at the same depth below the surface.

All care should be taken in the construction of a conduit-pipe, to avoid obstructions occasioned by lumps of folder hanging in the inside of the pipes, or by roughness at the joints, if the pipes are put together by screw-joints. All the cocks and plugs in the pipe should have water-ways fully equal to the section of the pipe.

Those who execute water-works are most tempted to fail in this point by making the cocks too small, because large cocks are very expensive.

The engineer should be scrupulously attentive to this, for a single contraction of this kind may occasion the extra expence of many hundred pounds in making a large pipe to be thrown away, because if the pipe will yield no more water than can pass through the small cock, it would have been as well to have laid a small pipe all the length.

It is of the most material consequence that there be no contraction in any part of a conduit, and it is also prudent to avoid all unnecessary enlargements; for when a pipe is full of water moving along it, the velocity in every section must be inversely proportional to the area of the section: hence the velocity is diminished wherever the pipe is enlarged; and it must again be increased where the pipe contracts.

This cannot be done without expending force in the acceleration; and consuming part of the impelling power, whether it be that of a column of water, or the force of a machine.

No advantage can be gained by the flow motion which takes place at every enlargement in a pipe; but every contraction, by requiring a restoration of the former velocity, employs a part of the impelling force; this force must be equal to the weight of a column of water whose base is the contracted passage, and whose height is sufficient to produce that velocity with which the water must pass through the contraction.

This point has often been overlooked by engineers of the first eminence; and has, in many instances, impaired the performance of their best works.

Another point, which must be attended to in the conducting of water through pipes is, that the motion of the water should not be by pulsations, but continuous. When the

water is to be driven along a pipe by the strokes of a reciprocating engine, it should first be forced into an air-vessel, that the elasticity of the confined air may preserve an uniform motion along the whole length of pipe. If the water is suffered to rest at every successive stroke of the piston, the whole mass must again be put in motion through all the length of the pipe. This requires a useless expenditure of power, over and above the force which may be necessary for raising or conveying the water to its destination. By employing an air-vessel and double or treble acting pumps we remove this imperfection, because it keeps up the motion in the intervals between the strokes of the piston. The compression of the air by the active stroke of the piston must be such as to continue the impulse during the momentary inactivity of the pump.

Pipes are subject to obstructions from the deposition of sand or mud in the lower parts of the pipes, and from the collection of air in the upper parts of their bendings. The velocity of the water should always be very moderate, and then such depositions of heavy matters are unavoidable; care should therefore be taken to have the water freed from all impurities, before it enters the pipe by proper filtration; and to discharge the sediment which is unavoidable, there ought to be cleansing plugs at the lower parts of the bendings, or rather a very little way beyond them. When these are opened, the water will issue with greater velocity, and carry the depositions with it.

It is much more difficult to get rid of the air which chokes the pipes, by lodging in their upper parts. This air is sometimes taken in along with the water at the reservoir, when the entry of the pipe is too near the surface; but it is easy to avoid this source of the air, by making the water enter the pipe beneath the surface. For if the entry of the pipe is two feet under the surface of the water at the spring, no air can ever get in, and a float may be placed over the entry, with a lid hanging from it to shut the pipe before the water runs too low.

Air is disengaged from spring-water by the motion of the water in passing along the pipe. When pipes are supplied by an engine, air is very often drawn in by the pumps. It is also disengaged from its state of chemical union, when the pumps have a suction-pipe of ten or twelve feet, which is very common. In whatever way it is introduced, it collects in all the upper part of bendings, and accumulates till it will choke the passage, so that scarcely any water will be delivered.

To illustrate this, suppose that the water of a spring, or collection of springs, is to be conveyed through a pipe to the place of delivery, at a mile or half a mile distant from the spring; and that the ground, over which the pipe is carried, has many undulations, and ascents and descents, where it passes over small intermediate hills and valleys. We will suppose the place of declivity to be but a little lower than the water at the spring, for example 9 or 10 feet. If the surface of the water in the spring comes down to the entrance-mouth of the pipe, or only near it, much air will run down with the water into the pipe; and wherever the ground rises in the course of the pipe, this air will lodge itself in the upper parts of the bends of the pipe, and thereby diminish the water-way so as to force the water to pass through a passage of one-fifth or one-sixth, sometimes one-tenth of the proper bore of the pipe when full.

Sometimes, though no air should get into the mouth at the spring, there will be these lodgments of air from the first running of the water; for when the water first enters into the pipe, if after coming down from the spring it has

to rise again, to pass the summit of a small hill, it will run over the eminence without carrying all the air before it, as it had done in other parts of the pipe, before it arrived at such eminence. Hence some air is left in the highest part of the bend, but the water which passes by the air runs forward and fills the pipe again in the descending part, and so goes on in a full bore, till it comes to the next eminence, where it again runs over the highest part of the rising pipe, leaving a space of air at top, which diminishes the water-way. Then filling the pipe full again, it proceeds till its next rising, and there the water-way is again contracted by the air.

To clear the pipe of this air, if the pipe is of lead, the common way, as practised by plumbers, is thus: at every rising ground the pipe is laid bare at the highest place, and a nail is driven into the upper side of the pipe, so as to make a hole through the metal. Whilst the nail is sticking in, the lead is hammered all round the nail, with the pen of the hammer, so as to make a little button or spout. When the nail is withdrawn, the air will blow out violently, till at last the water will succeed the air; and with a stroke or two with the face of the hammer the hole can be quite stopped up.

This is done at every eminence of the pipe, until all the air is discharged, and the full quantity of water will be delivered at the opposite end of the pipe. If the mouth of the pipe at the spring never receives any air, by the descent of the surface of the water, the pipe may give its full quantity for years.

The way to know when the whole water is delivered is to measure it, when the pipe has been fully cleared of air, as above-mentioned; and when by measure, the quantity of water appears to be deficient, the pipe must again be cleared of air or other obstructions.

If the spring is much higher than the place of delivery, the places where the air will accumulate in the pipe will not be just at the highest part of the pipe, but a little beyond it; because the water running with more velocity and force, drives the lodged air still forward down the pipe, and it must lodge in the part where the pipe begins to descend again, its own tendency to ascend to the top being counteracted by the motion of the water. In this case, the nail-hole must be made beyond the greatest elevation, or else the run of the pipe must be stopped for some time, so that the water may cease to be in motion, the air will then go back gradually to the highest part of the pipe, where it may be let out.

Suppose that the water, instead of coming from an elevated spring, be forced up its whole way from a place much lower by an engine, and up the conduit, then the places where the air will lodge will be beyond the eminences of the pipes, but nearer to the upper end. In these cases, it will not be sufficient to prick the pipe with a nail, because air will be continually forced in with the water, and will refill those places in the pipe from which the air had been emptied. The obstructions thus happening often occasion the bursting of the pipe, or it gives too small a quantity of water, and does damage to the engine.

In such a case, the following contrivance must be used; a small leaden pipe, about thirty feet in length, which is called a rider or air-pipe, is laid at the highest part of the main-pipe, and extends along the top thereof. It communicates with the main at the top of the eminence, and also at two other places, at fifteen feet on each side of the eminence. This air-pipe has a little branch and cock. Now if the cock is opened when the engine is working, the air will be pushed forward till it is discharged by the air-pipe and cock. If the air goes beyond the eminence, the pipe of

communication will certainly discharge it. When water comes out at the cock it must be shut, and the main-pipe will then be full of water, but after some time, the cock being left shut, air will gather again in the eminence of the main-pipe and lodge; but, if the air-cock is again opened, the air will be discharged.

When water is forced up by an engine into an elevated cistern, from which it is to run down a main-pipe to the reservoir where it is wanted, this air-cock will also be very necessary, because the water in the cistern sometimes covers the entrance-mouth of the descending pipe, and sometimes not. In that case, air goes down with the water.

In leaden or iron pipes of conduit, the discharge of air is absolutely necessary if there are any rises in the pipe. In wooden pipes the air often passes through the wood and escapes; but if the pipes are tight and thoroughly soaked, the air-pipes and cocks are very useful. When water runs from a raised cistern through a distance of a mile or two, some person should turn the air-cocks two or three times a day.

This trouble may in some cases be avoided, by carrying the air-pipe perpendicularly upwards, to an equal or greater height than the entrance mouth of the main-pipe. In this case, the water will rise up in the air-pipe to near the same level as the water at the entrance, but cannot run over. Nevertheless, if any air passes along the main-pipe, when it arrives at the air-pipe, it will rise up therein in bubbles through the water contained in the perpendicular air-pipe and escape. By taking advantage of some tall building, or large tree to support the perpendicular air-pipe, this expedient may in general be applied.

Defaguliers contrived a valve which should open to let out the air, and shut again when the water came. It was an inverted brass valve shutting upwards, and falling down by its own weight, with cork fixed to the under side of it, to make it rise and shut when the water came. This succeeded in first clearing the pipe of air, but it did not answer to keep it clear; because, when the valve had been shut some time, if air should extricate itself from the water, it would be dense air, whose force would be equal to that of the water, and would keep the valve shut as well as the water did before, although the air at first could not shut the valve. The only remedy for this difficulty is to make the valve very small, and make a hollow copper vessel for a float. This will rise with considerable force to shut the valve, when the water acts upon it; and it will be sufficiently heavy, when the water forsakes it, to pull open the valve.

The same author afterwards made a better contrivance. It is a small square box of cast-iron, made tight on all sides, except where the air-pipe communicates with the bottom of it, and also where a spout is fixed on the top to let out the air. This spout is provided with a cock, situated within side of the box, and to the plug of the cock a small arm or lever is fixed, having a hollow ball of copper at the extremity of the arm or lever. This ball floats on the surface of the water in the box, and when it rises opens the cock, or shuts it when it falls. When the air in the pipe accumulates, it passes along the air-pipe and enters into this box, and as the quantity increases, the surface of the water in the box subsides, until the float at the end of the lever, opens the cock and allows the air to escape, and this it will always do before any air can accumulate in the pipe.

It is best to place the air-box near to the main-pipe, but it must have communication by an air-pipe with the main-pipe, at two or three different places, in order that it may certainly receive all the air which gathers in the great pipe.

On the Discharge of Water by lateral Branch-Pipes from a Main-

Main-Pipe.—It is a common case in water-works, that water is required to be drawn off through a small pipe, from the side of a main-pipe, in which the water is not at rest, but in motion, with a much greater velocity than the flow occasioned by the water which is drawn off through the small pipe. It is often required to know what quantity such small pipe will yield. When water is passing along a pipe, its pressure on the sides of the pipe is diminished in consequence of its velocity; and if a pipe is derived from it, the quantity drawn off must also be less than if the water in the great pipe was motionless. It is therefore of great importance to determine what is the diminution of pressure which arises from the motion along the main-pipe.

It is plain, that if the water suffered no resistance in the main-pipe, its velocity would be that which is due to the height through which it had descended, and it would pass along without exerting any pressure. Also, if the pipe were shut at the end, the pressure within the pipe would be equal to the whole depth of water. Between these limits we shall find what we seek. If the head of water remains the same as when the pipe was stopped, and the end of the tube be contracted, but not stopped entirely, the velocity in the pipe will be small; and the natural velocity due to the descent being checked, the particles will re-act on what obstructs their motion. This action will be uniformly propagated through the fluid in every direction, and will exert pressure on the sides of the pipe. Now obstructions of any kind, arising from friction or any other cause, will produce a diminution of velocity in the pipe. The resistance, therefore, which we ascribe to friction, produces the same lateral pressure which a contraction of the orifice would do, provided that it would diminish the velocity in the pipe, in an equal degree.

We will first consider the case of an horizontal pipe, in which the whole impelling force is applied at one end of the pipe, either by a pump or by a column in a perpendicular pipe at that end. This force must be transmitted or carried by the water through the whole length of the pipe, wherein part of it will be absorbed in overcoming the obstruction and friction, and the remaining force will produce the velocity with which the water issues at the open end of the pipe. It is evident that every part of the horizontal length of such a pipe must bear a different degree of pressure, when the water is in motion; thus, at the end where it is discharged, there is no pressure exerted on the pipe to burst it open, because the water can escape freely; but at every other part a force must be exerted, which is sufficient to overcome all the resistance which the water will meet with, in running from such part to the open end, where it is discharged.

In short, whatever part of the column of water in the reservoir, or of the pressure which impels it along the pipe, is not employed in producing velocity, must be employed in acting against some obstruction; and by the re-action of this obstruction, an equal pressure is transmitted to all parts of the pipe. The chief questions will be, in what part of the pipe are these obstructions situated, and at what part is the force applied which is to overcome them; because that part of the pipe which is between the two, must bear the strain of transmitting the force from the place where it is applied, to the place where it is to operate.

In the case where the impelling force is all applied at one end of the pipe, and the only resistance is the friction of the water in running through the horizontal pipe, the pressure to burst the pipe, will begin at nothing at the open end of the pipe, and regularly increase from that to the other end. Its quantity for 100 feet in length may be ascertained for any given

bore of the pipe, and velocity of the water, from Mr. Smeaton's table of friction already given, and may be adapted to all other lengths by a simple rule of proportion.

If in addition to the resistance by friction, which takes place equally in all parts of the length of the pipe, there are any particular causes of obstruction at the extreme end or at any other part, the force necessary to overcome such resistance must be added to that required to overcome the friction, as found by the table; and all this tends to burst open the pipe, or that part which is between the impelling force and the obstruction, which may arise either from a perpendicular column or lift, up which the water is to be forced, or from a contraction.

Example 1.—A steam-engine with a forcing-pump is employed to force water through a pipe, which proceeds horizontally for 1800 feet, and then rises up 60 feet perpendicular, to a cistern at the top of a tower; the diameter of the pipe is five inches, and the motion of the engine is such, that the water moves with a velocity of 140 feet *per* minute through the pipe. It is necessary to supply a cistern in a house from the middle of the main-pipe, by a small branch-pipe of one inch bore and 100 feet long; this cistern is 55 feet above the great horizontal-pipe, or five feet beneath the elevated cistern; required the velocity with which the water will flow through the small branch-pipe, when the engine is not at work, and when it is at work.

When the water in the great pipe is motionless, there is the pressure of a column of five feet to force the water through the branch-pipe. Mr. Smeaton's table shews, that for one inch bore and 100 feet long, a pressure of five feet, or sixty inches, will produce a velocity of 180 feet *per* minute; but when this pipe is running, the water in the great pipe must move also. The area of the pipe of five inches, is twenty-five times as great as the pipe of one inch; therefore, the motion of the water in the great pipe, will be only one twenty-fifth of 180 feet, or 7.2 feet *per* minute. Find the nearest velocity to this in the table, or ten feet *per* minute, and under five inches bore, we find .07 inches the height necessary to produce that motion, if the pipe was 100 feet long; but as it is 960 feet, the height required will be $.07 \times 9.6 = .672$ of an inch. This should be deducted from the five feet pressure which urges the water through the small pipe; but so small a quantity is not worth notice: hence we may state the velocity when the engine is not at work at 180 feet *per* minute, and the discharge from a bore of one inch, will be .98 of a cubic foot *per* minute.

When the engine is at work, the same pressure will be exerted with the addition of all the pressure necessary to overcome the friction of the water, in running along the great pipe with a velocity of 140 feet *per* minute. Look for this velocity in the table, and for five inches bore it shews, that a column of 7.6 inches must be allowed for every 100 feet of the pipe. The length of the pipe measured from the place where the branch-pipe proceeds to the cistern at the top of the tower, is 900 feet horizontal, and 60 perpendicular, *viz.* 960; therefore, multiply 7.6 by 9.6, and we have 73 inches for the height, which must be added to the five feet, and makes 133 inches for the whole column or force, which urges the water to flow through the branch-pipe, when the engine is at work; lastly, by referring to the table in the column of one inch bore, we find that 135 inches will produce a velocity of 270 feet *per* minute, and the discharge will be 1.47 cubic feet *per* minute.

The same investigation shews us, that the main-pipe at the place where the branch-pipe proceeds from it, must bear the pressure of a column equal to 66 feet one inch when the engine

engine is at work, although it bears only 60 feet when it is at rest. But if we consider the whole length of 1860 feet, the friction will be equal to a column of eleven feet ten inches, so that the pressure, when the engine is at work, will be near 72 feet, at that end of the pipe which joins to the pump.

Example 2.—We will now consider the reverse of this case, that is, take away the pump and steam-engine, and let the water be propelled through the great pipe, by the water descending from the cistern, with a fall of 60 feet. What will be the pressure which causes the water to flow through the small branch-pipe?

To find this, we must calculate with what velocity the water will flow through the whole length of the great pipe, by the theorem and example we have already given for water in pipes. Having found this, calculating on the whole length of the pipe, we must make another calculation, reckoning only as much length of the pipe as is contained between the cistern of supply, and the place where the branch-pipe joins the main-pipe.

Then take the difference between these two velocities, and it shews what resistance or friction the water must overcome in running along the remainder of the pipe, *viz.* from the place where the branch-pipe joins to the open end of the pipe, where the water is discharged. Now if a simple orifice was to be made at that part of the great pipe where the branch-pipe joins, the water would flow out with a velocity equal to the difference of the two velocities, making the proper deduction for the friction of the water in passing through the orifice.

But if we wish to know the velocity with which the water will flow through the branch-pipe, we must find the depth of column necessary to produce the velocity equal to the difference of the velocities of which we have before spoken, calculating according to theory, without regard to friction; and then with the depth so found, we can seek in the table of friction in pipes, for the result or flow of water through the small branch-pipe.

The case of a regularly inclined pipe is considerably different, because the impelling force is not all applied at one end of the pipe; but every portion of the pipe having a descent, has also a portion of the impelling power applied to it. When this pipe is of a certain length, the water arrives as its maximum velocity without accelerating as it proceeds further down the slope; because the accelerating power of the water is in equilibrio with the obstruction, that is, the power of descent acquired in a foot or an inch of the slope, is just equal to the resistance in the same distance; consequently, the water exerts no pressure on the pipe to burst it open, any part of the water would continue to slide down the slope with its uniform velocity, even if it was detached from that water which followed or which preceded, and it derives no impelling power from any column of water. The effect would be just the same, if the pipe was split down the middle and converted into two open troughs.

It is clear, that in this case, no water can be obtained from any lateral branch-pipes, unless they descend from the pipe.

Let us consider the same pipe when the inclination is not a regular slope, but when some parts slope more rapidly than others. In this case, the impelling force is not applied regularly upon every part of the length of the pipe, as in the former instance; the consequence is, that in those parts which have a more rapid slope than the inclination of a line drawn from one end of the pipe to the other, the water will have a tendency to accelerate beyond the regular velocity which is due to the regular slope, and with

which it must ultimately flow out of the pipe; and on the other hand, in places where the slope is less rapid than this line, the tendency of the water will be to flow more slowly than the regular velocity. Now the pipe being close and of an equal bore, the water must flow with the same velocity in every part of the length; and although some portions of the contained water tend to run forwards faster than the regular velocity, yet other portions tend to hang back; by means of the pipe, the force is transmitted from one place to another, and these forces become all combined together to produce an uniform velocity.

We shall find, on farther consideration of these actions, that some parts may be subjected to a pressure or strain to force or burst it open, and other parts may at the same time be strained in an opposite direction, *viz.* to crush the metal of the pipe inwards.

Thus at every point where the pipe suddenly changes its slope or rate of inclination, from an easy slope to a very rapid descent, then the water will have a tendency to run down such sloping part of the pipe, and pass away faster than other water can come down the easy slope; the consequence is, that a suction or aspiration takes place within the pipe, and if a small branch-pipe were applied in such a situation, water may actually be drawn up from a considerable depth. This has been shewn by M. Venturi, who calls it the lateral communication of motion between fluids.

This is a certain proof that the bore of the pipe is too small at such places. An attentive consideration of these circumstances, will shew the propriety of making a long pipe with different bores at different places, where the slope is different; for, by judiciously increasing the bore of the pipe where the slope is less, the action may be made uniform throughout. But this cannot be done in cases where the changes of slope are excessive; for instance, when the pipe descends rapidly into a deep valley, and must rise again with a rapid slope in an opposite direction. This is the case with the pipes which supply Edinburgh, and in many situations is unavoidable.

The resistance arising from friction is greater or less according to the velocity of the motion; but whatever is the inclination of a pipe, provided it is long enough, the velocity with which the water runs through it will so adjust itself, that the sum of all the resistance in the whole length of the pipe, will exactly balance the sum of all the forces, which the water exerts by its descent. But if the pipe is too short, the forces of descent down the pipe may overbalance all the resistances. In this case, the water will tend to accelerate, and the water which has descended near to the bottom of the pipe, will draw after it that water which has just entered the upper part of the slope, instead of the water in the upper part, forcing forwards that water which is beneath it.

Dr. Robison observes that there are some curious circumstances in the mechanism of these motions, which makes a certain length of pipe necessary, for bringing it into the equilibrium of motive force, and resistance, which he calls *train*. A certain portion of the interior surface of the pipe must act in concert in obstructing the motion. We do not completely understand this circumstance, but we can form a pretty distinct notion of its mode of acting. The film of water contiguous to the pipe is withheld by the obstruction of friction, but glides along; the film immediately within this is withheld by the outer film, but glides through it, and thus all the concentric films glide within those around them, similar to the tubes of a telescope, when we draw it out by taking hold of the end of the innermost. Thus the

WATER.

second film passes beyond the first or innermost, and becomes the outermost, and rubs along the tube. The third does the same in its turn, and thus the central filaments will at last come to the outside, and sustain their greatest possible obstruction. When this is accomplished, the pipe is in train.

This requires a certain length of pipe which we cannot determine by theory; but it is evident that pipes of greater diameter must require a greater length, and this is probably in proportion to the number of filaments, or as the square of their diameter.

Du Buat found this supposition agree with his experiments. A pipe of one inch in diameter sustained no change of velocity by gradually shortening it, until it was reduced to six feet, and then it discharged a little more water. But a pipe of two inches in diameter gave a sensible augmentation of velocity, when shortened to twenty-five feet; he therefore says, that the squares of the diameter in inches, multiplied by 72, will express the length in inches necessary for putting the water in any pipe in train.

When pipes are of any considerable length, the waters of a larger pipe will run with a greater velocity than those of a smaller pipe having the same slope. A pipe of two inches diameter will give much more water than four pipes of one inch diameter; it will give as much as five and a half of such pipes, or more, because the squares of the discharges are very nearly as the fifth powers of the diameters.

On the requisite Strength for Water-Pipes.—We have shewn that, in certain cases, the water running through a pipe will exert little or no strain to burst the pipes. This may be the case in great portions of the length, or even in the whole length; nevertheless we may observe, that at all parts so situated, an open canal would answer all purposes as well as a close pipe. It is not necessary to employ a close pipe in any case, except where it is subjected to a strain. We may also observe, that it is prudent in all cases to make the pipe sufficiently strong to resist the full pressure of the impelling column, when the motion of the water is stopped; because this may happen accidentally, and then the pipe will burst.

In order to adjust the strength of a pipe to the strain, we may conceive it as consisting of two half cylinders joined by seams, parallel to the axis or length of the pipe; the strength of such seams to resist the separation of the two half cylinders will be equal to the ordinary strength of the materials of which the pipe is made. The inside pressure tends to burst the pipe by tearing open these seams, and the force which acts upon any given length of the pipe (as an inch or a foot), is the weight of a column of water whose base is the diameter of the pipe, by the given length (as an inch or a foot), and whose height reaches up to the surface of the water in the reservoir. This follows from the common principles of hydrostatics, and may be calculated by the rules for columns of water already given.

Suppose the pipe to be of lead, one foot in diameter, what will be the force to burst open one inch in length, at the depth of 100 feet under the surface of the reservoir? Water weighs $62\frac{1}{2}$ pounds per cubic foot, the base of the column is 1 foot by 1 inch, or $\frac{1}{12}$ th of a square foot, and the tendency to burst open an inch long of the pipe is $100 \times$

$$62\frac{1}{2} \times \frac{1}{12} = \frac{6250}{12} = 521 \text{ pounds nearly.}$$

Therefore, an inch long of each seam is strained by $260\frac{1}{2}$ pounds. A rod of cast lead, one inch square, is pulled asunder by 860 pounds. (See *STRENGTH of Materials*.)

Therefore, if the thickness of the seam is $= \frac{260}{860}$ inches, or

one-third of an inch, it will just withstand this strain. But we make it much thicker than this, especially if the pipe leads from an engine which sends the water along it by flarts.

M. Montgolfier states, that a pipe one inch in diameter, and one line in thickness, will bear a column of 50 feet, French measure, from which if we desire to know the proper thickness for any other diameter, with the same pressure, we shall find it by simple proportion. Thus, if the diameter be 4 inches, the thickness must be four lines; or if the pressure is augmented we proceed in the same manner, by direct proportion, so that for 100 feet it must be two lines thick for one inch diameter, and 8 lines thick for 4 inches diameter.

To make full use of this mode of reckoning, he gives the following table of the pressure which pipes of different substances will sustain.

	Feet high.
Copper pipe, 1 inch bore, and 1 line thick, will support a column of water - - -	400
Brass pipe of good quality, and the former dimensions	300
Lead pipe, made of sheet lead - - -	50
Cast-iron pipe, 2 inches bore, and 4 lines thick, will sustain at least - - -	500
Elm wood $1\frac{1}{2}$ inch diameter, and 2 inches thick,	30 or 40

That is, they may safely be made of that size, but will bear sometimes 110 feet pressure.

Lead Pipes.—The plumbers use cast pipes of lead, and also make pipes of tough sheet lead turned up, and burned or melted together in the longitudinal joints; the different lengths of lead pipe are sometimes burned together with lead at the joints, when they are laid in the field, instead of soldering, because this is much cheaper. Leaden pipes may be turned up of any size, but are not usually cast of more than four inches bore. Unless the cast pipes are very found, they are not so good as turned-up pipes; hence it is not advisable to use cast pipes of more than $2\frac{1}{2}$ inches bore. There must be great care taken in making the turned-up pipes, that they may be perfectly cylindrical.

Small lead pipes are made by casting and drawing them through a plate, like wire. See our article PIPES.

The proper thickness for lead pipes, according to Defaguliers, is as follows: a pipe, 7 inches diameter, situated from 140 to 80 feet below the reservoir, must be $\frac{3}{8}$ of an inch thick; that part which is from 80 to 60 feet beneath the reservoir, must be half an inch and an eighth thick; from 60 to 30 feet $\frac{1}{2}$ an inch; and the remainder from 30 feet up to the reservoir $\frac{3}{8}$ of an inch.

For pipes of four inches diameter, half an inch will do from a depth of 200 feet to 100 feet; from 100 to 40 feet depth $\frac{3}{8}$ of an inch thick; and from 40 feet deep up to the reservoir $\frac{1}{4}$ of an inch in thickness.

Defaguliers describes a method of proving the strength of pipes experimentally, by a small forcing-pump, to inject water into a piece of the pipe at one end, whilst a valve is applied to the other, which valve is loaded with such a weight as will equal the weight of the intended column of water; therefore, if the pipe bears this pressure, it will bear the column of water.

Lead pipes are very improper for water-works, where the water is forced by an engine; for at every stroke or push from the engine, the water raises the stop-valve of the pump, and

WATER.

and when the valve shuts again, the water falls with it, and gives a sudden blow against all the sides of the pipe. By the lateral pressure, this force acts in a direction perpendicular to the sides of the pipe, with the weight of a pillar of water whose base is the section of the pipe, at the place of the stroke, and the height is equal to the whole height of the water above that place; and it strikes with the same velocity that the valve falls. Now if the first stroke of this water makes the lead swell outwards but the 100th part of an inch, the lead having no elasticity, will remain in that position, and not shrink back; then suppose the next stroke swells the lead outwards the 100th part of an inch more, the diameter of the pipe will become so much larger and remain so. The next stroke will still make it wider, and so on for many strokes, till at last the lead becomes so thin that it must break. This is inevitable if the force is great enough to begin the enlargement, for after every stroke the force of the water striking will be greater than the preceding, in consequence of the enlargement, and will soon burst the pipe. An iron pipe is best to be used, for even if it were in itself as weak as the lead, it would not be liable to be enlarged, although each stroke should make it yield, but by the elasticity of the metal it would return again to its own dimension after every stroke. The same will happen in pipes of copper or wood, because those substances are elastic.

Wood pipes are made of elm or oak, bored through the middle with a succession of augers, increasing in size until the desired bore is attained. Belidor says a man can bore 39 feet of elm pipe, two inches diameter, in a day, but only 6½ feet of oak pipe. The manner of laying and joining pipes is fully explained in our article PIPE.

Care must always be taken that wood pipes are bored in the heart of the wood, and that the heart is of sufficient thickness about the bore of the pipe. Elm pipes of nine inches bore, that are from 80 to 140 feet beneath the surface of the water in the reservoir, must have the heart of elm three inches thick after it is bored: therefore, a tree must be chosen of no less than 18 inches diameter in the smallest part. For a depth from 60 to 80 feet, the heart must be 2½ inches thick, which a tree of 17 inches in diameter will afford; for a depth of from 30 to 60 feet, the heart must be two inches thick, and the tree 16 inches in diameter; and for any height under 30 feet, the heart need be but 1½ inch thick, for which a tree of 14 inches will suffice.

From these proportions it may be determined what thickness the heart of elm should be for pipes of less bore at the same depths, taking it thinner in proportion to the diameter.

Belidor recommends, in laying wooden pipes, to use a composition of mutton fat beaten in a mortar with powder of brick-dust, so as to make a sort of wax. When there are cracks in the wood, small wedges wrapped with tow, and covered with this composition, are to be driven in to stop them.

Earthen Pipes.—M. Belidor states, that the best kinds in France are made at Savigny, near Beauvais; they are in lengths of two feet, which enter three inches into one another, and are made of all diameters, from two to six inches; when the pottery is seven lines thick, they will bear a column of twenty-five feet of water. The joints are made of a composition of pitch, ashes, and brick-dust with mutton fat: this is applied hot; but for larger pipes, a cement of lime is used.

One of the lengths of the pipes for the supply of Edinburgh is made of pottery.

Iron Pipes.—The methods of joining and laying iron pipes will be found in our article PIPE; but we shall give a

TABLE of the Weight of Iron Pipes cast at Carron Iron-Works in 1769, being their Standard for dried Sand Castings, allowing every 36 Cubic Inches of Cast Iron to be equal to 10 lbs.

Diameter of the Infile, or Bore.	Full Diameter of the Flanch.		Length of the Pipe.	Thickness of the Pipe.	Weight of the Pipe.

13	1	11	9		11 0 26
14	2	0	9	11 2 7	

It was afterwards found that, in a long course of practice, it was better to make iron pipes rather thicker; because in moulding there is some uncertainty if the metal is equally thick all round.

WATER, Jets of, fountains were formerly the ornaments of all garden and pleasure-grounds; but are now so far out of fashion, that we only find them in the gardens of the greatest palaces.

The most celebrated are those of Versailles and St. Cloud in France, Frascati, near Rome, and Peterhoff in Russia. The subject of the latter is the contest of Jupiter with the Titans; it contains a column of nine inches diameter, which spouts sixty feet high.

The fountains of Versailles, which are very numerous and magnificent, are fully described by Belidor.

They consist of four grand pieces, which contain excellent bronze statues, representing some subject of the mythology, besides a great number of jets for the ornament of smaller pieces of sculpture. The basin of Latona consists of many jets, which throw up water obliquely 30 feet high, into three large basins, from which it pours down in cascades. The water-piece of Neptune and Amphitrite consists principally of perpendicular jets, which are very numerous. The basin of Apollo contains the god in his chariot, drawn by four horses; the great jets of this piece rise 57 feet, and the smaller jets 47 feet. The baths of Apollo contain most excellent sculpture, and large sheets of water in cascade. There are also the pyramids of water, mountains of water, alleys of water, theatre of water, &c.

We have no room left for treating this subject, which is of some intricacy, and shall conclude with Mr Mariot's table, which shews the altitude of a reservoir necessary to produce a jet of a certain height; and also the quantity necessary to supply jets of a certain-bore, measured in Paris feet and Paris pints, 42.36 of which are equal to a cubic foot English.

WATER.

See our article *JET D'EAU*, Vol. XVIII.

WATER, in *Gardening*, a well known useful article in gardening, as applicable to numerous sorts of young plants and trees, seed-beds, &c., especially in the droughty spring and summer seasons, both such as grow in the full ground and in pots in the open air, as well as those in green-houses, stoves, hot-beds, &c.: and also in ornamental designs, in pleasure-grounds, parks, &c., either when formed into regular pieces, circular, oval, or in oblong or serpentine canals, &c.; likewise when varied in a somewhat natural expanse, in curves and bendings.

In forming designs of this sort, the nature of the supply should be first considered, whether it be by springs in or near the place, by currents or streams passing through, or so nearly adjacent as to admit of being conducted to the place; or by being conducted by some neighbouring river, brook, or lake, &c. by means of pipes or small cuts, or by being collected issuing from higher grounds, and conducted by proper channels. And another circumstance, equally necessary, is to consider the means by which it may be retained afterwards. In a loose earthy, sandy, or gravelly bottom, it will soon sink away, especially in dry weather, unless there is a constant current or flow of water running in; but in a naturally strong clayey bottom, of proper thickness, both at the sides and below, it may be retained in some tolerable degree. In most cases, some art, however, will be necessary in this business. See *BASONS*, &c.

Where it is easily attainable in any of the above modes, it should not be omitted, on a smaller or larger scale, especially in grounds of any considerable extent; but where intended principally as reservoirs for watering gardens, they may be of much more moderate dimensions than when designed for ornament, and may be formed either in a circular manner, an oblong canal, pond, or cut, &c.; the stiffness of these forms being always broken by varying curves of the margins or borders, constantly forming them where the supply of water can be most conveniently procured.

Ornamental plats, or pieces of water in pleasure-grounds,

are very desirable, as being great additions to the beauty, variety, and embellishment of them, when properly disposed and contrasted with some nearly adjoining detached clumps of plantation, and bounded with a proper expanse of grass-ground, spreading from the verge considerably outwards. In general, when any spaces of water, on a larger or smaller scale, are intended, they should be disposed, as conspicuously as possible, in some principal division; either sometimes at or near the termination of a spacious open lawn, or occasionally in some other similar open space; and sometimes disposed more or less internally, in some central or other grand opening; in all of which an expanse of water has a fine effect. The particular forms may be adapted to the nature of the situation, and the extent to that of the supply of water that can be had.

In parks and pleasure-grounds, the most proper situations for plats, or other forms of water, are some rather low convenient places for containing and supplying it, which are so disposed as to display an agreeable rural view of the water from the residences and principal lawns and walks belonging to them, either near at hand, or at some considerable distance from them; and where there are occasionally other accidental sights and views of it, from other parts of the ground, unexpectedly taking place in an abrupt or sudden manner. In these situations the forms and appearances of it may likewise be greatly varied and diversified, according to their particular nature and other concurring circumstances, so as to take off any sort of formal regularity which they may have naturally. They may also have oval, oblong, winding, curving, or bending serpentine directions given to them, as may be the most natural and suitable; and they may be of small or very considerable extents, in proportion to the nature of the situations, and the sizes of the grounds, as well as the supplies of water which can be commanded. They are sometimes in large grounds, formed in the manner of natural bending rivers or streamlets, which sweep round rising swells of land, planted with trees in the form of clumps, or other modes, so as to produce a natural and agreeable effect.

Mr. London, in his ingenious work "On forming, improving, and managing Country Residences," thinks that water, in whatever point of view it may be taken, whether as necessary to the produce of a country, the delight of the traveller, or the interest of romantic rural scenery, is one of the most lovely ornamental materials of nature. Its effects in all these ways are highly useful, interesting, and beautiful; without it all soils are barren and unproductive, roads are dull and uninteresting to the tasteful traveller, and rural scenes are often tame and disgusting. For as it occurs in springy banks, purling rills, or winding brooks, it equally engages and delights; while in the more distant view, in larger expanses, as those of great rivers, glassy lakes, or the extent of the ocean, it exalts and fills the mind with astonishment. And in secluded country scenery it is not less successful in affording variety and pleasure, either by the beauty of its varied appearance, the roar of its fall among rocks and cliffs, the foam and din of it in the small cascade, or the melancholy of it in the stagnant pool, shaded by over-hanging boughs.

But though much has been ingeniously and usefully written on this interesting material of ornamental rural improvement, and the necessity and means of a better taste inculcated in the management of it, little alteration has yet been effected in the modes of practice, as few examples of artificial water rendered picturesque have been set before the public. The former old, naked, tame, shaven, formal methods, still continue to prevail too much in the distribution and

manner of conducting it. There are still not a few, who are infected with

— that strange disease —
Which gives deformity the power to please :

Collections of ornamental water may, it is said, properly be considered as of two kinds; as those designed to be seen in a general view, and in connection with the adjoining scenery; and those to be seen only when near. The former sorts chiefly consist of lakes, rivers, ponds, basons, and others of similar kinds; the latter of springs, rills, rivulets, cascades, and others of the same nature. There are scarcely any situations in which waters of the spring, rivulet, and others of the same nature, may not be placed. In nature, rills are usually found deep sunk in dells, as in instances where they run down the sides of hills, or pass through foils of the sandy kind. Where they pass through a fertile valley, or level meadow, they have commonly a very regular course; and when they are met with in hollow places, their course is for the most part straight, or approaching to it. The situations of rivers, lakes, and ponds, are almost invariably in the lowest parts of the surface of the land. It is, indeed, impossible that they could be otherwise. Water, whenever it occurs, is constantly a striking feature in grounds, and in this way has always its peculiar situation: when that situation is changed, every feature is perverted; truth, nature, and harmony, are set at defiance, and the most glaring discord substituted in their place, striking instances of which present themselves in many different ornamented situations.

The general shape of pieces of water must depend upon the nature of the character which is to be created or given them. Whatever may be the magnitude or dimensions of lakes or ponds, they should be of irregular shapes, more or less wooded, and never entirely naked, being constantly distinguished by prominences and masses; and as often as occasion may serve, further varied by islands managed in a similarity of manner. And the forms and directions of rivers should be given by their sizes, and the nature and kind of country through which they are to pass. Large rivers, in fertile plains, are, for the most part, much less varied in their courses than those of the smaller kind; and both are a great deal less so than those which have their directions through hilly uneven surfaces, or through land of a rocky nature. Large rivers can never be imitated where there does not exist a very considerable stream; as without this, the necessary degree of motion can never be given; but the directions or courses of natural rivers may, it is supposed, be frequently altered, varied, improved, or divided, with the most advantageous effects in the way of ornament; in all which cases the remarks here given will be applicable. Much might be effected in this way at many of the fine ancient seats of this country, and a high degree of grandeur and magnificence of effect be produced.

In regard to the margins or borders of waters, and the accompaniments of them, it is suggested that there are two arguments or reasons, which clearly shew that the former, in every piece of water, whatever may be its character, should be broken and diversified. The first of which is, that thereby intricacy, variety, and harmony in form, colour, and disposition, are produced, in the place of monotony or discord; the second is, that this mode prevails in nature. Intricacy, variety, and harmony, are produced in the outline, by making the small parts irregular, considerably so in some places, and less so in others, according to the kind of water; in the ground by producing breaks close to and also at some distance from the water; by shewing the naked or various-coloured earth and gravel interspersed among

abruptnesses, smooth slopes, levels, and by every form and disposition of surface: it is further heightened by the introduction of stones of different shapes, and placed in varied or intricate disposition; and also by roots, decaying trunks, or branches of trees. It is further suggested, that another fruitful source of these beauties is plants, grasses, low growths, shrubs, and trees. Plants and grasses may, it is supposed, be employed both for cloathing such parts of the surface as are smooth, for varying others, and assisting disposition. Shrubs and trees may be used for the last purpose upon a more enlarged scale. Plants, grasses, and low growths, give intricacy and shade to small breaks, and the interstices among stones, rocks, &c. Shrubs and trees give intricacy to large recesses, either of simple margin, or containing these lesser enrichments, which, shaded by trees, will be heightened in effect. All this, it is supposed, we see accomplished in nature in such a beautiful manner, as far surpasses every sort of description; it may, it is believed, be admired by persons of feeling alone, without much judgment or knowledge of the principles by which it pleases or produces the effect noticed; but this kind of knowledge and judgment is highly useful in directing what to copy from nature, and how to apply it to artificial pieces of water. Without it, persons, it is contended, may argue either for copying the deformities or singularities of nature, or for misapplying them when copied, as has been done by several. There is a difference of character in the margin and accompaniments of a lake, river, and brook, though each is varied or harmonious. Each differs also according to the nature or style of the country, or soil of the land through which they may have to pass, as is evident from a great number of different instances scattered over the country, in which there are particular differences in the banks, adjacent grounds, and accompaniments, that give an interesting variation of character to each individually.

There are some other ornamental appendages which are occasionally placed near to or upon water, such as erections of the bridge, and other kinds. There is no greater ornament to a piece of water of the nature of a river than a bridge, and few objects so generally pleasing, because so universally useful. This notion has been taken advantage of, it is suggested, by improvers, but for the most part in a very injudicious manner. Their bridges are too commonly formal, and unconnected with the scenery, either by their unsuitable magnitude, or by the loftiness of their arches, straddling across a shallow stagnated river, as is the case in many well-known situations. They want, it is contended, that beautiful simplicity, connection, and picturesque effect, which may be seen in many highway bridges across streams or rivers, and which is produced there by necessity and time. Thus the arches, it is said, are made low when the banks on each side are tame and level, because otherwise carts and carriages would have greater difficulty in ascending them. The architecture is simple, because, in general, the builders were not allowed to incur the expence of ornaments. The plants, ivy-bushes, and trees which group with them, have sprung up in the course of time, but they may be speedily imitated by art. The broken parapets, piers, or arches, supplied by open railing, or a few pales, are the effects of time, or accident, and in some cases are worth imitating in the scenery of a residence. These circumstances might easily be copied in ornamental scenery, and if judiciously supplied, it is said, will invariably succeed in producing a good effect. Foot-bridges of planks, or rude boles and trunks of trees, suit well, it is supposed, with many scenes of the rural kind. They have frequently been attempted, it is asserted, but seldom with complete success, owing to the tastelessness of those who contrived them.

The other sorts of erections which have been usually employed for the purpose of *ornamenting* water, it is contended, have rarely either picturesque effect, or any use; such, for instance, as those of aquatic temples, statues, river-gods, and other similar absurdities, or what may be called false decorations. Boat-houses, however, of simple constructions, and for the most part all useful sorts of erections, may occasionally be introduced with propriety and good effect. The Persian-wheel, the forcing-wheel, the corn-mill, and some others of similar kinds, are had recourse to with excellent effects in different places. "The water-wheel and corn-mill at Warwick-castle, it is said, is perhaps the grandest appendage to that noble building; whether in respect to the train of ideas which it awakens in the mind respecting its former compared with its present use, &c., or its effect in connection with the cascade, for which it forms an excellent apology. And though cascades of this kind be formal of themselves, yet the idea of their utility, it is supposed, compensates, in a considerable degree, for the want of picturesque grandeur; and still the *roar* meets the ear through woods, or distance, with the same force as in those which are natural."

Mr. London further supposes, that the picturesque improvement of the pieces of water which already exist will be attended to by all those who at present have artificial waters, in imitation of rivers, lakes, ponds, or brooks, and who are in the habit of making improvements of this kind upon their grounds. Such proprietors may, he thinks, be assured that no part can stand in greater need of alterations than such waters; and should they go on with others, except planting, to the neglect of this, they will not certainly merit the approbation of men of taste, as taste always prefers excellence to quantity. "If, it is said, any proprietor should hesitate to alter a piece of water which he has long been accustomed to see without being sensible perhaps of any great deformity, in consequence of habit, if he looks from his windows to a serpentine river, winding among smooth naked turf, with only here and there a few clumps placed at some distance from its margin; if the water presents one uniform glare of light, clear blue, or dull green, and seldom varied by any shadows or reflections but those of clumps and sky, let him, before he decides in favour of the tame river, imagine that in place of this a broad irregular lake, forming bays and recesses, retiring among thick woods, and with its margin in some places abrupt, broken, and varied by stones, plants, and creepers; in one place smooth, sloping, and covered with grais; and in another clothed with shrubs, trees, and low growths; then let him imagine that he sees these trees, woods, and the different coloured earths and stones of the banks, reflected upon the still surface of the water, which, in some places, was covered with dark shadows from the wood, and in others was bright and clear as the heavens: let him consider how interesting this would appear, even at a distance, and how long he might be employed in tracing with the eye the various recesses, dark places, and reflections; while still much remained indistinct or unseen, and therefore either employed the imagination in completing it according to its own ideas, or awakened curiosity to walk down and examine it minutely, by tracing, as far as could be done without the interruption of thickets and briars, the various windings and intricate margin of the whole. Let him only contrast this with the effect of the piece of water already there, which he can *see* and *know* as completely by a single glance as if he viewed it an hour; and could examine the two extremities, which are all that could be discovered by walking down to it, as completely in a few minutes as if he were to

encompass it a whole day. If the contrast does not strike him, he certainly, it is contended, as far as regards his own taste, is justified in preserving his water as it is; but if otherwise, he ought to commence improvement immediately, not only in gratification of his own sentiments, but also in justice to every attempt to promote and introduce good taste in a country where he is a proprietor, and among a people upon whom he is dependent for his rank and affluence. Different styles of improvement may, it is observed, be ornamental, and admired while they are in fashion; but it is only such as this, which are picturesque, or natural, that can stand the test of time."

The first thing to be considered in the alteration of artificial pieces of water, is the character which ought to be adopted; and the next, the execution of that character in the best manner possible, and with the least expence of labour and money. The former has been already fully noticed, and the latter will be particularly considered below. In many cases, however, the alterations required are so very simple, as to stand in need of little art, either in the designs or the practical parts, as has happened in altering the waters of different fine country-seats.

In short, the management of natural pieces of water, where they come within the province of picturesque improvement, mostly consists in rendering them more characteristic, and by the occasional introduction of *particular effects*. The leading principles in effecting the first of these improvements have been made sufficiently obvious already; and the latter are derived from what takes place in nature; as in the cases of waterfalls, cascades, springs, and drooping banks or rocks, on the margins of large brooks or rivers, all of which may, it is supposed, be imitated in particular instances. Also, in rills and smaller streams there are dank-pools, ponds, and little lakes, which often occur in their courses, that are highly worthy of imitation for their intrinsic beauty, their contrast with the narrow rills, and their use in landscape. Besides, it is suggested that a great advantage of such pools, or little lakes, is, that they may be made to appear natural where no other variety of still water could possibly be attempted. And that, in nature, they are found on the sides of declivities, where they are, for the most part, covered by wood, and seen only on a near view. In level places or situations, or such surfaces as are not strikingly inclined, they are or may be opened in some parts, for the purpose of being seen from distant places in the grounds, as is admirably done in some cases.

Another sort of occasional appearance or effect is *islands*, and they are particularly deserving of imitation, especially in lakes and ponds; nay, even in large rivers or brooks they have often a good effect. In large rivers they are mostly long and narrow; and in brooks frequently so large as to be wholly out of proportion to the stream, containing much extent of surface; but sometimes they are extremely small, and only contain a single bush, a few bushes, trees, or stones and plants; each of which cases may be seen in almost every brook, and they deserve imitation. Islands in ponds, it is supposed, should rather be numerous and near together, than large and distant, and be situated rather approaching the sides than the middle parts: the apparent magnitude of a piece of water may, it is suggested, be greatly heightened from the main point of view, by placing most of the largest islands next the eye, as well as by the mode of planting them. In regard to planting islands in general they should be wooded, but not wholly, and never in such a way as to exclude the appearance of surface, broken ground, rocks, roots, and stones, which

are more natural to islands than to shores, because it must always be supposed that it has been some of these materials which have either occasioned the accumulation of the island, or prevented it from being washed away afterwards.

Waterfalls and cascades are also occasionally introduced in extensive pleasure-grounds, where there is the advantage of a rivulet, by which they may be formed either in one large fall, or in two or three smaller ones in succession, having large rough stones placed below to break the water, and increase the sound of the torrent in its fall and passage over them, in some degree similar to that peculiar to natural cascades. And fountains, spouting water from images, &c. are sometimes introduced in the centre of small or moderate basons, or other reservoirs of water in gardens or grounds, where a supplying head of water is conveniently situated sufficiently high to raise and throw the water from the jet or spout, in a continued full stream, to a considerable height, which falling in the bason, keeps the water of it in motion, prevents stagnation, and is thereby rendered more proper for keeping and breeding fish of the gold and silver kinds, &c. and the spouting and falling of the water have a refreshing effect in the heat of summer. In parterres, shrubby grounds, and particular kinds of gardens, water is introduced either in the forms of still ponds, drooping fountains, or jets d'eau; but as these are all artificial, no perfect mode can be afforded for imitation. They, however, most of them proceed in some measure on the principle of contrast, which, in every modification of matter, is capable of producing either incongruity, variety, or harmony; consequently, of effecting scenes which shall disgust, please, or highly interest the beholder. Jets d'eau are not at present in such disrepute as they were formerly in this country; but they are, for the most part, less understood, and their proper use less comprehended.

Mr. London, in the above work, remarks, that the epithets waterfalls and cascades denote different characters in ornamental improvements. Where the water falls over a ridge of rock in one or more sheets, they are properly denominated waterfalls; and where its fall is broken and interrupted by the irregularity of the ridge, and by other fragments of rocks and stones, they are properly cascades. Both kinds, it is suggested, may be imitated in improved scenery, though hitherto this has seldom been well accomplished, on account either of the restricted practical knowledge of persons of taste, or the limited or vitiated taste, or deficiency of judgment, in those who have had the necessary practical experience in matters of this kind.

However, waterfalls may either, it is supposed, be imitated directly, by being copied from nature, or indirectly, by the introduction of weirs for the use of water-mills, as already hinted. In imitating nature, the strength or durability of the whole must be equally taken into consideration with that of the beauty. The first depends upon the general form of the whole materials, and the second principally on the foundation; but in a partial way also, on the quality of the materials, and the execution. In every case which is upon a large scale, the foundation ought to be the natural rock, if possible; but on a more moderate or small scale, it may be a secure causeway, fixed by oak piles and cross-planks, the work being performed with great care, and in an exact manner; using such mortar, where necessary, as is capable of resisting water.

It is noticed, that there is one variety of waterfall which may be occasionally seen in nature, and which is highly worthy of imitation, though it is not known to have ever yet been attempted to be introduced. It is that where a

small rivulet or rill, at its junction with a river or brook, falls over a rock in one small sheet. It is stated that, "at Matlock Bath, the noise of a small waterfall of this kind forms one of the finest circumstances of the scenery about that place;—borne upon the breeze, its grateful harmony meets the ear in almost every part of the adjacent scenery, in murmurs as varied as their passages through woods and open glades, along the surface of the Dove, under the echoing cliffs of the Tor, or ascending the heights of Abram. This remarkable effect, it is contended, produced by such a small quantity of water, ought to be the greatest encouragement to such as possess brooks or rivulets, as few cases can occur where it may not be imitated; not indeed with such remarkable success, because the surrounding scenery may not be so varied, but still with such an effect as would amply compensate for the expence, which in every case could be but trifling." Others are suggested, and the best manner of forming them clearly explained by drawn figures.

The nature of waterfalls for the purpose of driving machinery are, it is observed, generally pretty well understood; and that as no disguise in the masonry is requisite, but art is commonly to appear, the principles of strength and durability noticed above are what chiefly demand attention. But it is remarked that it is to be regretted that so few who have rivers take advantage of it, and that so many make cascades equally formal and unnatural, without any real use, and with little beauty, either of character in themselves, or fitness and connection with the scenery about them.

As to cascades, what has been said in respect to waterfalls will in general apply. In those which are upon a small scale, and where there is a plentiful supply of water at all seasons of the year, the same forms may be built with similar care in respect to foundation, solidity, and mortar, they being then disguised by rocks of different sizes in a natural manner, in different ways, according to the different circumstances of the places. The same general principles in relation to form will be applicable to all kinds of heads, fish-ponds, &c.; only in these cases the materials are commonly clay or gravel; which last should always be well puddled with clay or stiff loam on the side next the water. In designing waterfalls and cascades, one principal consideration is, it is said, to adapt them properly to the scenery. In some cases, they are quite inadmissible, as in all rivers or brooks without stones or rocks in their beds or margins; and in others where they are few, or where the ground on each side is level, they can never be made of any great magnitude. An attention to nature is, however, sufficient to guide us in this, as well as in every thing else which relates to the subject; a subject which, it is said, is so highly interesting and comprehensive, that it would require a very great space to give a complete elucidation of it in every respect. See *WATER-Falls*.

It may be noticed, that in the business of forming ground for water, the earth must be excavated to a proper depth, gradually sloping from the verge to the middle, from three to four or five feet deep; sometimes, however, in low situations, the place is naturally hollowed in some degree, so as not to require a general excavation, or only in particular parts, and some general regulations to the whole, which in extensive designs is a considerable advantage. Where the sides and bottom are of a sandy, gravelly, or stony nature, or abound in loose soil, and there is not a constant supplying stream, they must be well secured by the application of a thick coat of well-wrought clay. And where this claying is necessary in the preparatory excavation, a proper allowance should be made

made for the additional coat of clay, to the extent of twelve or fifteen inches in thickness, and of several inches of gravel over it, to preserve the clay from being wasted by the motion of the water, and keep it clear, which would otherwise be muddy. But previous to the claying, the loose and uneven parts in the bottom and sides of the cavity should be well rammed, to make the whole firm, even, and smooth; then beginning in the middle space with the clay, and proceeding gradually outward, being careful that no stones, sticks, or other matter, get mixed with it, to occasion fissures, or cracks, by which the water may escape, laying it evenly, a small thickness at a time, and spreading it regularly, treading it well with the naked feet; and if dry weather, casting water on it occasionally, ramming it well from time to time with wooden rammers; then gradually applying more clay, in the same manner, to the proper thickness, being careful that every part is so well puddled and rammed, as not to leave the smallest vacancy. Thus continuing the claying in a regular manner each way, from the bottom to the top of the circumference, smoothing the surface evenly, and in dry weather covering it, as the work proceeds, with mats or straw litter, or with the stratum of pebbly gravel. When the whole is finished, the water should be let in.

When this has been done, the top or verge must be regulated and levelled, forming it evenly from the edge of the water, in a gradual regular expansion to some extent outward, without any stiff slope close to the water, distinct from the surrounding superficies; laying the ground with grass turf, especially along the margin, continuing it as far down as the general level of the water. Where the extent is considerable it may be sown with grass-seeds.

In constructing the excavations for a body of water in such situations as are deficient of materials in some of their parts, as too low in some of their boundaries, as either at the ends or sides sinking below the general surface of the ground, or the height at which the water is intended to stand; these parts must be strongly banked up to the necessary height in a substantial manner, having a sufficient body of proper materials applied, especially where the part is to form a head at the end of a canal, or other similar piece of water; the whole being inwardly faced with a strong body of well puddled clay.

It is well known by every one, the above writer says, that the expence attending the formation of artificial water by the modes which have hitherto been chiefly practised is enormous, and in some instances scarcely supportable; but by adopting improved methods, such as those which have been suggested, it will in almost every case be greatly reduced, and become much cheaper, often to a very remarkable degree. This will be rendered quite evident by considering the different necessary operations in their formation, as they relate to each method of proceeding; such, for instance, as the excavation of the bed for the water, the formation of the head, the spreading of the earth taken out, and the management of the surrounding surface. In regard to the first, the principal reason why it becomes so expensive is, that a river is commonly imitated instead of a lake, which, on account of the natural slope of all grounds, requires not merely larger heads, but a far greater number of them. By in a great measure imitating lakes, one head is, for the most part, all that is required; and this also, many times, of a far smaller dimension than those in the cases of rivers. This alone often makes a very material difference in the cost.

In what relates to the spreading of the excavated earth, and the regulation of the surrounding surface, as in the me-

thods hitherto pursued in landscape gardening, whatever may be the natural character or tendency of the surrounding surface, it is to be reduced, by levelling, to a smooth, even lawn, or pasture, sloping in a gradual manner from the margin of the water. This of course causes a prodigious expence of money; and what is still more disagreeable, it is too frequently quite uncertain, and only capable of being calculated after the finishing of the whole work. The quantity of cubical yards to be removed in the work of excavating can be estimated very nearly to a certainty; but the business of levelling is intricate, troublesome, and often of great extent; hence the great excess of expence which is frequently incurred beyond the estimate in this respect in pieces of made water. If any one plan ever had the advantage over another, it is contended that certainly picturesque or natural pieces of water have the full and complete superiority over those of other kinds in what regards expence. In them, it is maintained, the natural character of the ground is preserved or improved, and consequently no expence of levelling is incurred; the superfluous earth produced in the process of excavating being formed into irregular inequalities, or distributed along the banks in such a manner as to augment or increase their character and picturesque-ness, as is evident in numerous instances. Under other circumstances, vast expence may often be run into, without much, if any, beauty being produced; when it could have been effected to a great extent by the modes which are here advised without laying out much money. Farther information on this very interesting subject may be gained by consulting Mr. London's excellent work.

WATER, Rain, Collecting of, for Farm Use, in Rural Economy, the providing it in proper situations for the purpose. This practice was formerly adopted in different parts of the country: as in most towns, and in the yards, ponds for the use of cattle, are still to be met with, which have an artificial appearance. In extensive pasture heavy or about the houses of many old farm-lands, pools or land districts, pits have evidently been formed by art for the purpose of catching such rain-water as may be brought to them by the ridge-furrows, ditches, or other such means, as well as that of land-springs. The art too has been long practised on the southern chalk-hill parts of the kingdom, and still continues, in a great measure, to prevail; and on those, in some northern districts, it has been more lately established, and spreads itself on the neighbouring heights with vast benefit. It is certainly necessary and useful in all dry high situations. It may probably, in some cases, also be collected into such pits, from the roofs of the buildings, for such purposes, with much advantage; though it has been much too common to draw it up, at great labour and expence, from deep wells formed in the bowels of the earth.

Lately much more attention has been bestowed on this matter than was formerly the case, in most places, and in some with the greatest success and benefit. It should never be neglected where the want of it is considerable, as livestock never do well under such circumstances. See *POND, Made STREAMS,* and *WATERING Live-Stock.*

WATER, Sea, Management of Land gained from, in Agriculture, the bringing ground of this sort into cultivation. It has been observed, that the principal difficulty that can occur in any situation will be to keep off the water of the rivulets or rivers that may come from the surrounding lands, and to carry away and deliver to the sea the surface-water collected from the land gained: the next important consideration is that of clearing this land of surface incumbrances. It will often happen, it is said, that the ground

to be defended is intersected by a river. This is, it is thought, the most expensive and difficult case that can occur; but it is here only necessary to carry the defence along each side of it to the sea; and there, where it intersects the other line of defence, to place a flood-gate, which may prevent the tide from entering, except when it may be necessary to admit vessels or other things, and which shall allow the water of the river to pass into the sea. Small rivulets and springs may either be turned along the margin of the land gained, and be let out at one end of the defence where it joins the land, or be led the most convenient way to one or more of the valves or flood-gates, which it is necessary to make in all defences for excluding the water within. The water collected on the surface of the land gained, may generally be let off by the above flood-gates or valves; but where the defence is extended into the water, this cannot be the case, as the level of the sea will mostly be above that of the land. In this case, wind-mills for driving pumps must be placed at proper distances, according as the particular case may be. Perhaps, in general, one small wind-mill driving four pumps, may be sufficient for freeing a thousand acres of ground of water. The expence of such a pump-mill would not, it is said, be above twenty or thirty pounds. By making a small defence-bank, from two to four feet high, some distance within the larger one, all the water collected between that and the original shore would be accumulated; and it might be led in a raised canal in the same level to a flood-gate in the outer defence. This would, it is thought, leave very little water to be drawn up by the pump; and in this way, though twenty thousand acres were gained, one wind-mill only would be necessary. Often, and indeed in most cases, in place of a wind-mill, the brooks, rivulets, or springs collected within, might easily, it is said, be made to turn a water-wheel, which would be more permanent and uniform than that turned by the wind. A basin might also be constructed, so that the ebb and flow of the tide would turn a draining-wheel; and a great many other methods might, it is supposed, be successfully adopted. Thus, in land gained from the sea, there cannot, it is thought, be any difficulty in preserving it from water, from whatever quarter it may come. When the land to be gained is more or less covered with stones, these should be put in flat-bottomed boats at low water; and when the tide floats them, they should be rowed to the proposed line of bank defence, and be then dropped. This mode of conveyance will generally be found the most economical for all the solid materials which are at a distance. Where the ground is sandy or poor on the surface, and argillaceous earth or rich loam below, it may be trench-ploughed to such a depth, as to turn up the good and bury the bad soil. If the soil be shallow, and even rocky, it may still, it is said, be rendered valuable. The most rocky parts may be covered five or six inches deep with mouldy matters, and the whole be sown with either meadow grass-seeds, to be floated with fresh water, or kept as meadow; or with other proper and suitable grass-seeds, and kept as salt-marsh. When mud of a good quality and considerable depth is gained, it may, in some cases, it is thought, be desirable to summer-fallow it for one or more seasons, after it has been secured from the sea. At other times it may be better to sow it with rape-seed for the first season, and to summer-fallow it the next, as a preparation for a corn-crop, &c.

It is observed that no sort of land can be gained from the sea but what is of great value for the purpose of cultivation, and especially as it can for the most part be flooded by fresh water as well as by that of the sea at all times. By flooding, the most barren sand or rock, with only an inch or

two of soil upon it, will bear excellent pasture. Indeed, much of the sand in these situations that is often reckoned barren and useless, is mixed with broken shells, and on being examined will be found to contain three or four parts in ten of calcareous matter. Most of the large rocks, too, within the salt-water mark are, it is said, in a state of rapid decomposition, and so fragile on the surface, as to be easily penetrated by the roots of grass-plants; more particularly after they have been exposed for some length of time to the action of the atmosphere. The large detached stones often found within the water-mark are not here meant, as these are supposed to be either buried in the ground, or boated off as above; but those continued rocks which frequently constitute the basis of the sea-shore for great distances, the surface of which is so completely oxydated, and occasionally decomposed and reduced so as to be called *rotten*, that they are capable of affording either an excellent manure for certain soils, or are fit and proper for supporting the vegetation of saline plants in their actual condition.

The quantity of land of this sort that is easily capable of being obtained and thus cultivated is very considerable indeed, perhaps not less than some millions of acres in the whole island. See *WASTE Land*, and *WATERING Land*. Also *SALT-Marsh*.

WATER, Gum. See *MUCILAGE*.

WATER, Hungary. See *HUNGARY Water*.

WATER, Laurel. See *LAUREL*.

WATER, Lime, is common water, in which quicklime has been slaked. See *LIME-Water*.

WATERS, Ophthalmic, or Eye, are such as are good in disorders of the eyes. See *COLLYRIUM, EYE, and OPHTHALMIA*.

WATER, Tar. See *TAR-Water*.

WATER, in Anatomy, &c. is applied to divers liquors, or humours, in the human body.

Such is the *aqua pblegmatica*, plegmatic water; which is a ferous fluid contained in the pericardium.

WATER, in Geography and Hydrography, is a common, or general name, applied to all liquid transparent bodies, flowing on the earth.

In this sense, water and earth are said to constitute our terraqueous globe.

Some authors have rashly and injuriously taxed the distribution of water and earth in our globe as unartful, and not well proportioned; supposing that the water takes up too much room.

The quantity of water on this side our globe, Dr. Cheyne suspects to be daily decreasing; some part thereof "being continually turned into animal, vegetable, metalline, or mineral substances; which are not easily dissolved again into their component parts." *Philosoph. Princip. of Relig.*

Many modern philosophers are of the same opinion.

An inundation, or overflowing of the waters, makes a *Deluge*; which see.

WATER, among Jewellers, is properly the colour or lustre of diamonds and pearls; thus called, by reason these were anciently supposed to be formed, or concreted of water. The term is sometimes also used, though less properly, for the colour or hue of other precious stones.

WATER is also used in divers ceremonies, both civil and religious. Such are the *baptismal water, holy water, &c.*

WATER, Holy, is a water prepared every Sunday in the Romish church, with divers prayers, exorcisms, &c. used by the people to cross themselves with at their entrance, and going out of church; and pretended to have the virtue of washing away venial sins, driving away devils, preserving from

WATER.

from thunder, dissolving charms, securing from, or curing diseases, &c.

The use of holy water appears to be of a pretty ancient standing in the church: witness St. Jerom, in his life of St. Hilarion, and Gretser, de Benedict. cap. x. &c.—M. Godeau attributes its original to Alexander, a martyr under the emperor Adrian.

Many of the reformed take the use of holy water to have been borrowed from the lustral water of the ancient Romans: though it might as well be taken from the sprinkling in use among the Jews. See Numbers, xix. 17.

Urban Godfrey Siber, a German, has a dissertation, printed at Leipsic, to shew, by proofs brought from church history, that one may give holy water to drink to brutes.

Bitter Waters of Jealousy.—In the Levitical law, we find mention made of a water, which served to prove whether or no a woman were an adulteress. The formula was this: the priest, offering her the holy water, denounced, "If thou hast gone aside to another, instead of thy husband, and if thou be defiled, &c. the Lord make thee a curse and an oath among thy people, by making thy thigh to rot, and thy belly to swell; and this water shall go into thy bowels, to make thy belly to swell, and thy thigh to rot." And the woman shall say, *Amen.* "These curses the priest shall write in a book, and blot them out with the bitter water. When he hath made her drink the bitter water, it shall come to pass, that, if she be defiled, the water shall enter into her, and become bitter, and her belly shall swell," &c. If he be not defiled, she shall be free, and conceive seed." Numbers, chap. v.

WATER, Interdiction of Fire and. See INTERDICTION.

WATER of Flax and Hemp, &c. that which is used for steeping or raising them in, in the view of procuring the pure vegetable fibrous matters that they contain. The writer of the "Elements of Agricultural Chemistry" has observed, that this water possesses considerable fertilizing powers. It appears, it is said, to contain a substance analogous to albumen, as well as much vegetable extractive matter. It putrefies very readily. And that as a certain degree of fermentation is absolutely necessary for obtaining the matters of the flax and hemp in a proper state; the water to which they have been exposed should on that account be used as a manure as soon as the vegetable fibres removed from it.

WATER, Black, a disease in neat cattle and sheep, which is not unfrequently of a serious nature. It has not, however, been yet properly or fully investigated.

In neat cattle it is said to arise from sudden changes in the state of the weather from heat to great cold, the taking of cold on being turned into low wet pastures in the early spring season, and the want of proper water in long dry times. Some suppose too that it may be caused by fresh pastures of particular sorts, and that certain vegetables picked up by the cattle may produce it. It consists of a discharge of a dark black bloody nature from the kidneys, and sometimes probably from other parts of the body. It is most probably produced by inflammation terminating suddenly in a state of great debility and relaxation of the parts, so as to admit the dark grumous blood thrown out to pass away in this manner.

In slight cases of this nature the cattle do not seem to be greatly affected by the disease, but where the bloody fluid passed away is considerable, and lasts for some length of time, the animals become reduced to a very low state or condition, and great weakness is the consequence, which if not speedily removed by some proper remedy, the cattle soon sink under the pressure of the complaint.

In the cure, except the disease be taken at its commencement, bleeding will seldom be useful or necessary, but the bowels should be well cleared out by powerful evacuating remedies of the salt kind, and kept properly open by their repetition, so that the cattle do not become in the least constipated, which would be hurtful and dangerous. When the discharge continues, balls composed of alum, rust of iron, and armenian bole, made up with Venice turpentine, may often be of service, when given in sufficient quantities; but a more powerful and effectual remedy will be found in a strong decoction or infusion of bark, with vitriolic acid, and the tincture of opium, given in the proportion of a pint of the first, two drachms of the second, and three drachms of the last. This may be repeated once or twice in the course of the day where necessary, the bowels being always well kept open.

By some of these means the disease may mostly be removed without any great difficulty.

Some think that much benefit often arises from the use of nitre in full doses in this disorder, as well as from the change of pasture, in some instances, as from low to such as are rather high in their situation.

In *sheep* the disease is characterized by much the same appearances, taking place suddenly, most commonly among those of the hog kind, and such as are apparently strong, while feeding in rank pastures of the clover or other luxuriant grass kinds. In these cases, there is sometimes much dark bloody watery fluid met with in the stomachs of the sheep after death. The disease in these animals is mostly very rapid in its progress, therefore the sheep in such pastures should be constantly well looked to, in order to discover if any of them be indisposed.

In the prevention of the black water in these animals, some have found great benefit by the use of about half a tea-spoonful of sulphuric or vitriolic acid in mixture with a small spoonful of the compound tincture of cinnamon, when given in a cup of cold water to each sheep in the morning, and cotting or housing them in the night season.

In other cases, when the disease appeared to be present, much advantage has been said to be produced by giving a strong infusion of oak-bark with aromatics, well acidulated with the sulphuric acid, and to which has been added a little of the tincture of opium. The bowels are to be kept in an open state at the same time.

The immediate removal of the sheep into closer fed and drier pastures, will always be attended with great benefit in this disease, and the supplying them with dry food might perhaps in some cases be of utility.

WATER, White, a name often given to a dangerous disease in sheep.

WATER in the Head, a denomination frequently applied to a disease in the head of sheep. See GID and STURDY.

WATER Braxy, among *Animals,* a disease in sheep, which has been disputed by some; but which the writer of the "Shepherd's Guide" is confident exists, having seen and dissected several cases of it after death; and is assured, too, that it does considerable damage on some particular farms, in some situations; but that whether it be a species of the common braxy or not, will, it is thought, admit of a doubt, though it is always viewed and considered by the shepherd as such. It is stated in addition also, that in two external appearances it has a resemblance to it. The first of which is, that the animal, when living, seems affected much in the same way, lying frequently down, and loitering behind the rest of the flock, appearing likewise somewhat swelled in the body. And that the next is, that, like all others affected with the braxy of any kind, it will not bleed

to any extent on opening a vein. The cutting of a vein in the tail, spould, or below the eye, will make other sheep bleed plentifully; but from these scarcely a drop will issue; and even on cutting the principal vein in the throat, only a very small quantity, it is said, proceeds to flow out.

However, in the interior appearances it differs very widely and materially. On opening the sheep, the whole entrails are, it is observed, swimming in bloody water, none of which is within the bowels, but only within the rim of the belly. The gall-bladder is very small, appearing as having been mostly spilled previously to the death of the animal, and the urinal bladder is contracted and shrunk up to a size scarcely noticeable. The small fibres connecting it with the other parts are inflamed, and on bringing it near the nose smells somewhat like the other braxy. The bladder seems entirely without urine, but on blowing it up it is always quite sound, and never bursts; the guts and flesh are a little discoloured, and have a smell peculiar to that disorder. The smaller department of the stomach or *reid* has some purple spots on it; and, on being felt with the finger, these are thicker in the texture than the other parts of it. They seem, too, to have bled a portion inwardly; this some suppose issues from the liver.

In an essay inserted in the appendix to the Rev. Mr. Findlater's Account of the Agriculture of the County of Peebles in Scotland, it is said to be a disease that is analogous to the suppression of urine, which is caused by the want of sufficient activity and exertion. And that it consists in the bladder being over-distended with urine, which raises violent inflammation in that organ, and produces an incapacity to discharge the urine that is accumulated. The consequence of which is, that the urine regurgitates over the body; the whole carcass is tainted by fetid gases; the bladder becomes gangrenous, bursts, and the animal dies. That young and vigorous sheep are most liable to this sort of braxy. And that the immediate cause of the disease is feeding too freely on rich succulent diuretic food, and resting too long in the morning on the layers, taking place frequently when the shepherds are more negligent than usual in removing them.

It is supposed that the disease may be prevented by avoiding too free an use of succulent diuretic food, and by moving the animals from the layers on which they are early in the morning, making them walk about for some time in the view of encouraging them to pass their urine and purr.

In attempting the cure, in case the bladder be greatly distended and affected, which may be known by there being a great fulness in the lower part of the belly, the urine may be endeavoured to be drawn off by the introduction of suitable implements of the catheter kind, or by cautiously letting it off by incision or puncture, where that cannot be done. In either of these ways, when effected, great relief will be afforded.

And in the view of allaying or preventing inflammation, the use of proper purging and evacuating injections should be had recourse to, such as Glauber, or other salts of the same kind; or even warm milk and water be thrown up.

The first writer, however, thinks that no remedy for the disease has yet been pointed out that can be fully depended upon. See BRAXY, and STRIKING *Ill, Blood, or Sickness*.

WATER Farcy, a disease in horses of the œdematous or partial dropical kind, which is often very troublesome in its removal. It has no relation or resemblance, however, to that of the real farcy, being wholly different in its nature, causes, and effects, though sometimes ignorantly supposed

to be of the same kind. It occurs in horses of all kinds and descriptions, and at most periods of their existence. It is a soft watery swelling below the skin, and is caused by whatever has a tendency to weaken and destroy the natural vigour and strength of the body, whether in a local or general manner, but more especially in the former, such as low bad keep, want of sufficient cleaning and dressing, taking the animals into cold water in a warm state, too great exposure to cold rains, and many others. It often, too, happens after severe colds of the epidemical kind. The swellings take place in different parts, but particularly in the legs, having a pitted or dimpled appearance when pressed by the finger. In some cases, the disease has a more general dropical aspect, the water not being confined to any one part, but shews itself in several, over the whole body, by such swellings. These cases, for the most part, proceed from foul feeding, or the effects of eating too greedily of rich luxuriant after-grass. In the former case, the limbs and the whole body are sometimes seen enormously swelled, and become very hard, the belly and sheath parts being very greatly distended.

In the cure of the disease, in all the cases, the great objects are the removal and discharge of the water, and the prevention of its future formation by every possible means. The former are to be attempted by the giving of strong diuretic purgative remedies, and the latter by the use of medicines of the strengthening kind, so as to brace up and restore the tone of the relaxed solids of the whole body.

In the first of the above intentions; the combining of calomel and squills with jalap and aloe, in the proportions of about one drachm each of the two first, to two drachms each of the two last, for a large horse, may be very useful, when made into a ball, and given every night, or every other night for four or five times, and repeated as there may be occasion; throwing in, in the intervals, bark and other tonics, in full quantities, to restore and keep up the strength of the animals.

Rather strong infusions of the fox-glove with aromatics may likewise be tried, and oak-bark in powder, with the same, be given in large doses at the same time they are made use of.

The horses should frequently, too, have good mashes in which nitre has been put.

Gibson, however, advises the horses to be purged once or twice in ten days, and to have intermediately a pint night and morning of the strong decoction or infusion of black hellebore, prepared by boiling or infusing it in water, and then adding to four parts of it two of white wine, that has stood upon the same for some length of time in a warm state; or a ball composed of nitre, squills, and camphor, in the quantities of two drachms of the first, three drachms of the second, and one drachm of the third, made up with honey, and given once a day, either alone, or washed down with a hornful or two of the above infusion.

The horses should be kept warm, and have plenty of dry food while they are under these courses of medicine. See FARCIN.

WATER Sickness, a disease among sheep of the dropical kind. It is a disorder, or sort of affection, arising in the weak states of their constitutions, which is incident to all the varieties of soil and climate, it is said, in its different forms and degrees of violence, from Shetland in the north of Scotland, to the most southern parts of this country, wherever sheep-husbandry is carried on. It is observed to occur, in general, among aged sheep, that are subjected to its attacks in consequence of weakness, either of the more general or more local kind. It most commonly seizes the animals towards

the end of the harvest-season and winter, and on farms which are mostly destitute of shelter. It is, in fact, said to be the genuine offspring of cold and moisture, and perhaps of every thing that debilitates the vigour of the animals.

The appearances that distinguish it to be present are swellings in the legs towards night, which disappear in the morning, when the lower jaw often becomes a good deal swelled. The eyes are dull, the urine, when noticed, is high coloured, the tongue is dry, and as the disease advances, the belly often becomes tense, and water is felt undulating in it, especially on being struck on one side with one hand, while the other is kept steady on the other side. The sheep lose their heart and vivacity, their appetites fail them, they become thin and lean, and at last fall away and die.

In regard to the prevention of the disease, a dry well-sheltered sheep-walk is said to be good in that intention; and the neighbourhoods of sea-shores are useful in the same view, as have been found by experience. But if the distemper should shew itself in a severe manner, in very wet seasons, in winter or spring, night-shelter is found of particular benefit in stopping the increasing state of the malady. The animals, too, should have good, green, sweet, dry hay chopped and given them, at the same time with a little oats or bran in some cases.

In the cure of those which are diseased, a shed or room in a house, and a full allowance of the same sorts of dry food, are particularly necessary and useful. Some have tried tapping in the advanced stage of the disorder, but with only a temporary relief. Two drachms of cream of tartar given twice a day, in a little warm thin oatmeal-gruel, have been known to have a remarkably good effect. In the more early stages of the complaint, small quantities of calomel with squills would probably remove the disease, especially if accompanied with a few hornfuls of a strong decoction of oak-bark two or three times a week. By these means, diseased sheep, when taken early, would perhaps be readily restored.

In the above-named part of Scotland, the disease is said to be called by the title of shell-sickness, as well as that which is here given it.

WATER-Calamint, in *Botany*, the name used by some for a species of mint. See MENTHA.

WATER-Crowfoot, in *Agriculture*, the name of a plant of the weed kind, on which cows are said by some to be very fond of feeding. And in the fifth volume of the Transactions of the Linnean Society, Dr. Pulteney has observed that it is not only relished by swine, but that they thrive remarkably upon it, requiring little or other food until put up to fatten. The produce of it cannot, however, be great, so that the use of it must be limited.

WATER-Cress, in *Gardening*, the common name of a small creeping plant of the herb kind growing in watery situations, such as the sides of rivulets, rills, brooks, or other small trickling streams; and which is much employed as a salad herb, and for eating with bread and butter, or in other modes in its natural state, as being highly cooling and agreeably bitter. See CRESS.

WATER-Dropwort. See DROP-WORT.

WATER-Germander. See GERMANDER.

WATER-Hair-grass. See AIRA AQUATICA.

WATER-Hemp-Agrimony. See WATER-HEMP-AGRIMONY.

WATER-Leaf. See LEAF.

WATER-Lily. See NYMPHÆA.

WATER-Melon, the vulgar name of a plant of the melon kind, growing in aquatic situations, and the fruit of which is of a watery insipid nature. See CUCURBITA CITRULLUS.

WATER-Parfnep. See PARSNEP.

WATER-Poa. See POA AQUATICA.

WATER-Soldier, a species of *Stratiotes*; which see.

WATER-Tath, in *Sheep Husbandry*, a term applied to that sort of rank grass that arises from an excess of wetness in sheep-walks and pastures, and which has a tendency to produce the rot in these animals. It may be caused by too much wetness in the lands, either naturally, or by the use of water on them. It is this probably that makes water-meadows so dangerous for sheep at certain periods. See TATH and WATER-MEADOW.

WATER-Hen, in *Ornithology*. See FULICA CHLOROPUS, FLAVIPES, and RALLUS CAROLINUS.

WATER-Ouzel. See STURNUS CINALUS.

WATER-Rail. See RALLUS AQUATICUS, and BENGALENSIS.

WATER-Wagtail. See WAGTAIL.

WATER-Dog, in *Zoology*, a variety of the CANIS FAMILIARIS. See DOG.

WATER-Elephant. See HIPPOPOTAMUS.

WATER-Hog. See CAPIBARA.

WATER-Rat. See MUS.

WATER-Aidle, in *Agriculture*, a term applied to the stagnant water contained in moss land, in some places, as in some parts of the county of Lancaster. It is said to be highly prejudicial to animals, when they drink water that is mixed or impregnated with it. It is best removed from such land by proper draining, and frequent suitable tillage cultivation.

The bringing such wastes into a state of improvement consequently discharges it in an effectual manner. See MOSS and WASTE LAND.

WATER-Bailiff. See BAILIFF.

WATER-Barrow, *Swing*, in *Rural Economy*, an improved contrivance of this sort. See QUENDON WATER-BARROW.

WATER-Bearer, in *Astronomy*. See AQUARIUS.

WATER-Bellows, in *Mechanics*, a machine used to blow air into a furnace, by the action of a column of water falling through a vertical tube. The orifice where the water enters the tube is so contrived, that the water shall be mixed with air when it enters the pipe; and this air will be carried along with the stream through the tube, and is collected into a proper receiver, from which it is conveyed to the furnace in a continued blast. These machines are much used on the continent, but have never been introduced in England, because they will not produce by any means so great a current of air as may be raised by the same fall of water, when employed to work bellows, or other machines, by means of a water-wheel.

M. Reaumur has given a minute description of the water-bellows employed for the iron furnaces, in the provinces of Dauphiné and Pays de Foix, in France, where such machines are called *trompes*. The water is conducted to the furnace by a trough or passage, having an inclination of one inch in a toise; the body of the trompe is a vertical tube, about 27 French feet in height, and 16 inches diameter on the outside: it is made of two pieces of fir hollowed out, and bound together by hoops of iron.

The form of the interior of the tube contributes materially to its effect. The mouth or upper orifice, where the conduit-trough pours the water into it, is 13 inches diameter; from this it diminishes, in the manner of a conical funnel, till at a depth of three feet from the mouth, it is only four inches diameter, which part is called the throat. Here the opening of the tube enlarges all at once to a size of nine inches, which it continues for all the rest of the height. Immediately beneath the throat, (that is, the upper part of the

WATER-BELLOWS.

the tube where it becomes nine inches diameter,) ten vent holes are bored through the sides of the tube; they are cylindrical, and two inches diameter; their direction is inclined, so that they point downwards at about an angle of 45 degrees; they are arranged at equal distances round the tube in two rows, the upper row having six holes, and the lower row four: it is through these holes that the air enters. The tube is supported in a vertical position by a framing, and the lower end is introduced into a strong ton or cask, six feet deep, and almost as much in diameter, though it is rather smaller at top than at bottom. The tube descends through the head of the cask 18 inches, so that it terminates within $4\frac{1}{2}$ feet of the bottom of the cask; and a kind of table made of a flat round stone, or a plate of cast-iron, is placed horizontally in the centre of the cask, at 18 inches beneath the orifice of the tube, being supported by a cross of wood, placed upon four legs, from the bottom of the cask. The cask is well closed on all sides, particularly round the tube, where it passes through the head; but there is an air-pipe conducted away from the top of the cask, to convey the air to the furnace; and from the bottom of the cask there is an opening, by which the water can pass away. The opening is regulated by a wooden shuttle, which pens up the water to such a height within the cask, that the opening through which the water issues will be always beneath the surface of the water, so as to prevent the escape of the air by the same passage.

The action of this machine is not so easy to explain as its structure, and it has at various times occupied much of the attention of philosophers. Father Kircher was the first who described the machine in his *Mundus Subterraneus*; but he did not satisfactorily explain the reason of its action. In the *Memoires des Scavant étrangers*, Barthes, the father, has given a theory which is very defective; and Dietrich was of opinion that the air was produced by the decomposition of the water.

M. Reaumur explains it thus:—The funnel of the tube is always full of water, which issues rapidly through the throat; but finding immediately a larger place, the stream disperses and scatters into drops, because it is no longer enclosed within a cylindrical surface: it does not, therefore, take any constant figure, but the stream is composed of different small streams, or rather successions of drops, which are continually changing their position with respect to each other. Now the intervals between these separate streams or drops are occupied by the air which is within the cavity of the tube: suppose that between two streams separated by air a third comes to descend, it will push the air before it with all its force, and carry the air down to the cask; and this will be replaced by fresh air, entering at the vent-holes. The irregular arrangement which the streams or drops take, either at their issuing from the throat or in continuing their fall, is such that few drops do not carry some air down before them into the cask: the water falling upon the table within the cask dashes on all sides, and releases the air which rises in the cask, and issues through the air-pipe to the furnace, whilst the water falls to the bottom of the cask, and escapes gently through the sluice.

A single trunk of the dimensions just described is found sufficient to blow a forge or finery; but for a smelting furnace, three are joined together, having a common trough of supply, and the air-pipes from the three casks are joined together. M. Reaumur supposed that a greater height of the fall would produce more air, because it is longer exposed to those changes of position in the different streams of water; but he supposed that no adequate advantage would be gained by an increase of the diameter of the tube, because

it would be more likely, in falling in a large body, to descend in a closer column.

The machines of the Pays de Foix are somewhat differently constructed: in these the water is conveyed into a reservoir, from the bottom of which a square trunk or tube descends to the reservoir or air-chest, which is made very long; and the air-pipe proceeds from an elevated part of it, to prevent the danger of spray or small drops being carried into the furnace. Instead of a throat and the vent-holes, the tube is made to divide into two branches, at the point where it passes through the bottom of the upper reservoir: these branches rise above the surface of the water in the reservoir, so that it cannot enter into them, but the water is admitted at an opening between these two branches, so that in effect the tube is divided into three, the centre being an opening for the water to descend, whilst the two outside branches admit the air to mix with the water and go down.

The editor of the *Art des Forges* supposes that the vent-holes are useless, but that the violent agitation of the water in passing the throat, and dashing upon the table within the cask, is sufficient to change the water into air. This is the same hypothesis as that of Dietrich.

These various explanations rendered the subject still more obscure; and in 1791, the Academy of Toulouse invited philosophers to determine the cause and the nature of the stream of air which is produced in these machines. M. Venturi, professor of philosophy at Modena, gave the real answer in an excellent paper on the principle of lateral communication of motion in fluids.

To explain the principle, this philosopher supposes a number of equal balls to roll along in a horizontal trough, in contact with each other, with an uniform motion at the rate of four balls in a second: suppose, on arriving at the end of the trough, they fall suddenly to a depth of 16 feet. Now, from the laws of gravity, each ball will perform this descent in a second of time; and as four balls succeed each other in each second, it follows that there will always be four balls in the air at the same time. The relative positions of these will be as follows: the uppermost ball will be one foot from the point where they begin to fall, the second four feet, the third nine feet, and the fourth sixteen feet. This arises from the acceleration which always takes place in descending bodies. A consideration of this circumstance will give a proper idea of the disunion and successive separation of the particles which the accelerating force of gravity produces in fluids, or in bodies which fall in a stream.

The rain-water flows out of gutters by a continual current; but during its fall, it separates into portions in the vertical direction, and strikes the pavement with distinct blows. The water likewise divides, and is scattered in the horizontal direction. The stream which issues out of the gutter may be one inch in diameter, and strike the pavement over the space of one foot. The air which exists between the vertical and horizontal separations of the water which falls is impelled, and carried downwards. Other air succeeds laterally; and in this manner a current of air or wind is produced round the place struck by the water. M. Venturi went to the foot of the cascades which fall from the *Glacière of La Roche Mélon* on the naked rock at *La Novalèse*, towards mount *Genis*, and found the force of the wind to be such as could scarcely be withstood. If the cascade falls into a basin of water, the air is carried to the bottom, whence it rises with violence, and disperses the water all round in the form of a mist.

He formed one of these artificial blowing engines of a small size; the vertical pipe was two inches in diameter, and

WATER-BELLOWS.

four feet in height: it was a plain cylindrical tube, without any throat or funnel. But he found, when the water accurately filled the section of the orifice, and all the lateral openings of the pipe were closed, the pipe no longer emitted any wind.

According to this writer, the circumstances which favour the most abundant production of wind are as follows:—The separation of the descending balls is more rapid in the upper than in the lower part of the fall. In order, therefore, to obtain the greatest effect from the acceleration of gravity, it is necessary that the water should begin to fall at the orifice of the vertical tube with the least possible velocity, and that the depth of the water in the horizontal trough should be no more than is necessary to fill the section of the vertical tube. The vertical velocity of this section is supposed to be produced by a height or head of water in the trough, of a depth equal to the diameter of the tube.

We do not know by direct experiment the distance to which the lateral communication of motion between water and air can extend itself, but we may with confidence assume that it can take place in a vertical tube, whose section is double that of the original section with which the water flows from the trough into the pipe. Let us then suppose the section of the pipe to be double the section of the water in the trough, and in order that the stream of water may extend and divide itself through the whole double section of the pipe, some bars, or a grate, are placed in the orifice of the vertical tube, to distribute and scatter the water through the whole internal part thereof.

Since the air is required to move in the blowing-pipe with a certain velocity, it must be compressed in the receiver. This compression will be proportioned to the sum of the accelerations which shall have been destroyed in the inferior and close part of the vertical pipe, that is, the part beneath the vent-holes. Taking this closed part of the pipe $1\frac{1}{2}$ foot, we shall have a pressure sufficient to give the requisite velocity in the air-pipe. The sides of this portion of the pipe, as well as those of the receiver, must be exactly closed in every part, to prevent the escape of the air.

The lateral openings in the upper part of the pipe may be so disposed and multiplied, particularly towards the top, that the air may have free access within the tube.

In some machines of this kind, the constructors seem to have been of opinion, that a great height was required in the water-fall; but Dr. Lewis, who made a great number of experiments upon the subject, shews that an increase in height can never make up for a deficiency in the quantity of water; four or five feet, he thinks, is a sufficient height for the water to fall: and where there is a greater height, it may be rendered useful by joining two or more machines together in such manner, that when the water has once committed its air in the condensing cask or vessel, it shall flow out into a new reservoir, and from thence descend through another funnel and cylinder, and fall from it into a condensing vessel, where the air is extricated and carried off through the air-pipe.

Another kind of water-bellows was invented by the ingenious Martin Triewald, of Sweden, and is described in the Philosophical Transactions. The machine consists of two casks or tuns open at bottom, and so loaded, that they will sink into water in the same manner as diving-bells. These being so suspended that they can be alternately lowered down into water and drawn up again, will by proper valves and pipes afford a continual blast of air.

Fig. 15. *Plate Water-works*, represents these water-bellows in profile. A A are two casks, made nearly the same shape as diving-bells, being in the form of a truncated cone, or

wider below than at top, where they are furnished with close heads B B, but at the lower ends A A are quite open. In the heads B B are valves V, which open inwardly, and are made like the palates of other bellows, with their hinges and the valves themselves covered with hatters'-felt. They are cauled to shut by easy steel springs till the air from above opens them, which happens only when the bellows receive their motion upwards. The valves are shut by means of the pressure of the air within, when they sink down into the water.

On the same heads two pliable leather tubes R R are fixed, one at the top at each water-bellows, which tubes are made and prepared in the same manner as those used in water-engines for extinguishing of fire. These leathern tubes or pipes reach from the bellows to the tubes T T, which carry the wind into the furnace, or any other place, according to pleasure.

These two bellows are suspended from the lever by iron chains K K, which are fastened to two sweeps S S, by which means they hang perpendicular from the balance-beam, and at the same distance from the centre of its motion C on the opposite sides. On the top of this balance-beam are fixed two sloping gutters F F, into which the stream of water runs from the gutter G, and gives motion to the whole work, performing the same service as an overshot or any other water-wheel; but they cost much less, and give as even and regular motion as a pendulum, for as soon as so much water runs into either of the inclined planes of the gutters F F, that the weight of the water exceeds the friction near the centre of motion C, and the weight of that bellows which is sunk down into the water, the gutter immediately descends with an increasing velocity till the balance meets with the resistance of the wooden springs H H; during this time it has raised the opposite water-bellows, or that bellows which is fixed under the opposite gutter, the gutter which has been filled being come down to the spring H, delivers all the water it has received, and at the same time the water begins to run into the opposite gutter, which receives its load of water almost as soon as the former is emptied, so that one of the gutters begins its effect as soon as the other has finished, and this continues alternately as long as the stream of water is supplied. These sloping gutters upon the balance-lever, therefore, perform all the effect which a water-wheel does in working the ordinary bellows, and by means of the same power of descending water, but acting reciprocally on opposite ends of the balance-beam.

These water-bellows blow the fire on the same principle, which produce the effect of the ordinary bellows, viz. that the air which enters the bellows, and which they contain when the top is raised, is again compressed or forced into a narrower space when the bellows close; and since air like all other fluids moves to that place where it meets with the least resistance, it must consequently go through the opening which is left for it, with a velocity proportioned to the force by which the air is compressed, and must blow stronger or weaker in proportion to the velocity with which the top and bottom of the bellows are made to approach each other; the blast also will last a time proportioned to the quantity of air that was drawn into the bellows through the valve or pallet.

The same operation takes place in the water-bellows, for the air which they contain must necessarily be compressed by the water, which rises alternately into the bellows A A, and obliges the air to go through the leathern tubes R R, as being the place where the air meets with the least resistance.

In this machine, the chief part of the weight to be moved

moved is balanced in equilibrio, for the bellows A A may be considered as two nearly equal heavy weights in a pair of scales, which in a great part balance each other. The difference is occasioned by that bellows which sinks down into the water, being so much lighter, as it loses its weight by the quantity of water it displaces, from the bulk of air contained beneath the surface of the water. This difference is compensated by the weight of the water which falls down along the sloping gutter, which acquiring the power of a falling body, increases in the same proportion as the bellows to be raised by it increases in weight; for the bellows which sinks down into the water does not at once lose its weight in the water, but gradually as it descends deeper; and in the same manner, the ascending bellows does not at once become heavier than the other, but the weight gradually increases from the time it is first raised till it is quite raised.

Mr. Hornblower some years ago proposed an hydraulic bellows of the same kind as M. Triewald's, except that, to avoid the flexible tubes of leather R R, he employed a lead pipe to go down to the bottom of the cistern of water in which the bellows descended, and turn up again beneath the bellows, so that the orifice of the pipe was above the surface of the water; it therefore communicated at all times from the interior of the bellows to the furnace. Mr. H., in Nicholson's Journal, mentions a very striking difference between these water-bellows, in which the moving chest was eighteen inches square and moved perpendicularly nine inches, and a common pair of smith's leather-bellows of thirty inches long.

The leather-bellows threw considerably more air to the fire, and its nozzle, compared with the water-bellows, was as 73 to 60 in diameter, but it did not produce so great an effect in bringing on the heat; and the noise of the water-bellows was so great as to almost drown that of the common one. The only difference in other respects is, that in the hydraulic bellows, the pipe went under ground for about eight feet, and the connecting pipe of the other came down about the same distance from the shop above.

WATER-Bomb, a name given by our chemist Godfrey to a machine he invented on the plan of Greyl's discovery, for the extinguishing of accidental fires in houses. He considered first, that the unchangeable size of Greyl's engine was a very great objection, and on this plan contrived a medicated liquor, which was such an enemy to fire, that a very small quantity would extinguish as much as a much larger of common water; and this liquor had the farther advantage, that it might be kept ever so long without corrupting, and by that means the vessels containing it would remain always fit for use; whereas in Greyl's method they must have been rotted by the corrupting and fermenting of the water, after a few years. The author of this invention tried it twice in public with us, and both times with all the success that could be wished; but the structure of the vessel was so much the same with that of Greyl's, that Godfrey cannot be allowed any farther merit as an inventor, than that of contriving the medicated liquor instead of common water. The machine is a wooden vessel, made very firm and strong, that the liquor, when once put in, cannot leak out any where; in the centre of this is an oblong cylindrical vessel, which is filled with gunpowder; a tube is brought from this to the head of the barrel; and this being filled with combustible matter, and the inner case with powder, and both made of plate-iron, that no water may get in, the vessel is then filled with the medicated, or antiphlogistic liquor. The top of the tube is then covered, and the thing set by for use.

When there is occasion for it, it is only necessary to uncover the tube, and setting fire to the matter in it, it is conveyed to the vessel containing the powder, and the whole machine being thrown into the place where the fire is, is torn to pieces by the explosion, and the extinguishing liquor scattered every way about, on which the fire is quenched in an instant.

The contriver of these things proposed the making of three kinds of them, the one containing five gallons of the liquor: this was the largest size, and contrived for the largest rooms, and most urgent necessities. The second kind contained three gallons; and the smallest, which was meant for a closet, or other little room, contained only two gallons. Those of the smaller kind also had sometimes a peculiar difference in their structure, the powder-vessel being placed not in the centre, but at the bottom: the intent of this was to fit them for chimneys, when on fire, as by this means the liquor, not being wanted to be scattered on all sides, was carried mostly upwards. These were fixed on the end of a long pole, and by this means thrust to a proper height up the chimney; and the tube that communicated the fire was placed downwards.

The manner of using the machines for rooms on fire, is this: the person who has the care of them is to throw them as nearly as may be into the middle of the room, and then to retire to a little distance: as soon as he hears the explosion, he may safely enter the room, and with a cloth, or any thing of that kind, put out any remaining sparks of fire that there may be in particular places. If the room be so large, that one of the machines cannot disperse the liquor to every part of it, two are to be used, one being laid at each end: and if several rooms are on fire at once, as many of the machines are to be used, one being thrown into each room. If a whole house is on fire, the lower rooms are first to be taken care of, and after these the upper, as they ascend.

Our Godfrey had scarce better success than his predecessor Greyl; for while he was making his public experiments, one Povey, collecting some of the fragments of his broken vessels, found out the ingredient used in the medicated liquor, and made and sold the things in the same place where he had proved his right to them. It is probable that the medicated liquor was no other than common water, with a large quantity of sal ammoniac, that salt having this virtue of extinguishing fire in a very remarkable degree. But it is to be greatly wondered at, that while all the world were convinced by experiments of the use of the machine, the author made but little advantage of it, and it is now disused. *Act. Erudit. Ann. 1724, p. 183.*

The society of arts and manufactures, &c. made trials of balls prepared in Mr. Godfrey's method, by his grandson, in a proper edifice erected for this purpose; and they found, that, after the fire had prevailed for a considerable time, and the flame forced its way through the chimney and windows, it disappeared, and was entirely extinguished by the explosion of two of these balls. See *FIRE, Extinguishing of.*

WATER-Borne, in the *Sea-Language*, denotes the state of a ship, with regard to the water surrounding her bottom, when there is barely a sufficient depth of it to float her off from the ground; particularly when she had for some time rested thereon.

WATER-Camblots. See *CAMBLET.*

WATER, Cataract of. See *CATARACT.*

WATER-Clock. See *CLEPSYDRA.*

WATER-Colours, in *Painting*, are such colours as are only diluted

diluted and mixed up with gum-water: thus called, in contradistinction to *oil-colours*. See WASHING.

The use of water-colours, makes what we call LIMNING; as that of oil-colours does PAINTING, properly so called.

Painters in water-colours have been often afflicted with the disease called colica pictonum, occasioned by the poisonous quality of several of the pigments which they use; and which, by putting the point of their pencils between their lips, whilst they are studying their subject, they insensibly swallow. Dr. Fothergill says, that, when the vomitings are abated, copious discharges by stool are procured, and the functions of the bowels in a degree restored to their usual state by the method pursued in the cure of the colica pictonum; nothing contributes so effectually to restore the use of the limbs, when impaired by these causes, as the liberal and constant use of the tinctura guaiacina volatilis; which may be given in such quantity, as to keep the body gently open; mixed with a little common sugar or honey, and then diluted with any weaker mucilaginous liquor, as thin gruel, or barley-water, or marshmallows-tea. Med. Obs. vol. v. p. 394.

WATER-Cisterns, for *Rural Purposes*, such as are formed for different domestic uses. In high, dry, upland situations, cisterns of this kind are of great utility and importance in many parts of the country. In the account of the agriculture of the North Riding of Yorkshire, it is stated that in the high eastern parts of it, water-cisterns or reservoirs are made by the inhabitants within the ground, which are highly useful: these, it is said, are fed by the rain-water which falls upon the roofs of the buildings, and is conducted from thence by spouts. That in these cisterns a very ample supply of soft water is always ready at hand; and that by their being under ground, and kept close, the water is sweet and suitable for every domestic or other use.

A water-cistern of this sort is stated to be formed in this manner. A cube of the required size being dug in the ground, and the sides made even and perpendicular, the bottom is covered with so much clay, as that, when well beaten, will be four inches thick; a foundation of stone is then laid round the sides; upon the clay, a brick floor is laid in terras, the surface of which should not be lower than the top of the foundation; the sides are then built a single brick thick, and the bricks laid in terras, a foot space being left betwixt the wall and the earth, which is gradually filled with clay in a soft state; and this well beaten as it stiffens; the whole is arched over, leaving a hatchway for a man to go in and clear it out, and an opening or passage into a drain, for the surplus water to run or be taken off, when the cistern is full.

The water is raised for use by means of a pump. In these cases, as keeping all external air out of the cistern contributes, it is said, much to the sweetness of the water; the pipe by which the cistern is fed should be continued to within a few inches of the bottom, and the surplus water be conveyed off by a pipe rising from near the bottom to the extreme height the water is designed always to be at, when that takes place, and there communicate with the drain: by these precautions, it is said, there will be no more of the surface of the water exposed to the external air, than what is within those pipes and that of the pump.

This method of forming water-cisterns may be found useful, cheap, and convenient, in many places, where such water is necessary to be preserved pure and sweet.

Cisterns of this sort have sometimes the title of water-cellars, and are of great convenience and use for farm-yards. See WATER, River, Collecting of, and WATERING Live-Stock.

WATER-Courses, in *Agriculture*, are such large ditches or passages for taking off the water as are formed, and remain constantly for the purpose in different places, and properly belong to the public.

They should be kept constantly well opened and cleared out, not having too much fall given them, so as to destroy the evenness of their bottoms. See SEWER.

WATER, Cut. See CUT-WATER.

WATER, Dead, in *Sea-Language*. See DEAD-WATER and SHIP-BUILDING.

WATER-Engine, in *Mechanics*, denotes either an engine to raise water, or any engine that moves by the force of water.

WATER-Falls, in *Ornamental Gardening*, are those falls of water which are formed and introduced in pleasure or other grounds for the purpose of producing ornamental and picturesque effects, or which naturally exist in such situations. They are of different kinds and forms, being sometimes of the nature of cascades, and at other times contrived for the intention of driving some particular sort of interesting machinery, so as to afford an agreeable and striking picture in the rural scenery of the particular place where they are had recourse to. They are usually constructed, where they do not exist naturally, either by means of large rocky stones thrown rudely together into a sort of ridge form of head, over which the water passes, formed in the way of weirs, or built in masonry in a careful and exact manner, according as the different nature of the circumstances and situations may require. See WATER.

Mr. London, in his useful work on "Country Residences," has well described and delineated several different modes of forming water-falls. They should, he thinks, be natural, strong, and lasting, from the general form of the whole of the materials, the security and solidity of their foundations, and the quality of the work and materials used in building them.

WATER, Foul, in *Sea-Language*. See FOUL.

WATER-Fowl. See FOWL.

WATER-Furrow, in *Agriculture*, a deep open furrow drawn by the common or a large double mould-boarded plough made for the purpose, in a proper direction of the field in arable lands, or those in the state of tillage, for the use of conveying and taking off the superabundant hurtful water, and preventing the stagnation of it from injuring the crops. This is especially necessary and proper in the winter season, and often in others. It is therefore essential that, as soon as possible after sowing most sorts of grain, but particularly wheat, when there is any disposition in the soil or land to the retention of moisture in too large a proportion, there should be as many water-furrows opened in this way as may be sufficient for carrying off and completely removing the excess of water, and thereby preserving the ground in a properly dry and sound condition for the healthy growth of the crops. It is observed by the writer of a late Calendar of Husbandry, that the making of proper water-furrows is a circumstance of much importance in the culture of wheat, but that it is oftentimes strangely neglected. It is a work, however, that should be well and effectually performed on all lands, except those that are perfectly dry all the winter through. The water-furrows should be formed by the plough, as soon as the field has been finished ploughing, sowing, and harrowing, and then a spit of earth should be dug from out of the bottoms of them, and laid on one side opposite the rise of the land or ridge, and the loose mould in the bottom parts be well snowelled and cleaned out, so as to make a perfectly free passage for drawing off the wetness; the openings of all the common ridge-furrows being

being likewise well cleaned at the same time, so that the water may have an easy fall out of every one of them into the large water-furrows. The number of these large furrows must constantly depend on the variations of the surface, and some other circumstances of the lands: the only general rule is to make them so many in number, as that no water may be suffered to stand on any part of the land in the wettest weather. In the bottoms or low parts of fields, or in other places of them where there is a double slope of the land, it is necessary to form and cut double water-furrows at the distance of about a yard or four feet from each other, in order to take the water from each descent singly.

The same writer, too, farther advises, that in all lands sown with clover or other grasses among the corn, these sorts of furrows should be dug a spit deep, and the mould raised in that way be carefully thrown out. Many farmers, it is said, are not attentive enough to this point. They only scour the furrows in such cases. They should, however, it is thought, consider how long the grass crops are on the ground, which may be two or three winters; consequently it must be very material to such crops to lie dry all that length of time, which scouring alone will not effect, at least not in a sufficiently perfect manner. Particular attention should also be paid to the spreading of the earth that is dug out of the furrows in these cases, as if the men be not cautioned, they will lay it too thick and injure the crops; it should be chopped and rendered small, and then spread with great care, in order that the seeds may rise freely through it.

In the case of arable land, these furrows should be often examined during the winter season, to see that they are perfectly open and free; the clods, lumps, and other such matters that may have fallen into them, being cleared out by means of the spade.

This is a practice which is either much overlooked, or very imperfectly executed, in a great many districts of the kingdom. The sides of the furrows in these cases should always be made to stand firm, and to have a good slope each way, which prevents their falling in and mouldering down so much. The name of water-furrow drain is sometimes given to this sort of furrow. See *WATER-Furrowing*.

WATER-Furrow Fall Plough. See the next article.

WATER-Furrowing, a term used to signify the operation of opening water-furrows. It is a sort of work mostly executed by the assistance of a large plough for the purpose and the spade, but sometimes by the plough alone. And in some parts of the county of Essex, particularly in the neighbourhood of Colchester, they have a method of doing it by means of a machine that is termed a fall-plough: in the lines where this sort of furrowing is to be performed across the fitches or ridges, this sort of tool is used there once in six, seven, or eight years, for the purpose of lowering, or, as they call it, *falling* the surface. They first gather four or six furrows by the plough; then follows this implement across these furrows, in their loose fresh ploughed state, taking up the parts of the mould, and dropping them on the crowns or sides of the fitches or ridges, and when finished, the water-furrows are ploughed and scoured in the common manner: the invention is said to have merit, as the water certainly takes a freer course than in the usual method. In a dry season, a large extent of ground can be done in a short time, at little expence, in this way.

Some think this work done in the neatest and most effectual manner by means of a shovel; and that an old worn shovel is the best for the purpose. See *WATER-Furrow*.

WATER-Gage, the name of a simple contrivance for measuring and ascertaining the depth or quantity of any water

in its application to any purpose, or otherwise. See *GAGE*.

WATER-Gang, a term applied to a channel or passage cut through any spot to drain and free a place of water by carrying off a stream from it.

WATER-Gavel, in our *Old Writers*, a rent paid for fishing in, or other benefits received from, some river.

WATER-Gilding. See *GILDING*.

WATER-Lanman, a small glass instrument, which is a tube of about three-quarters of an inch in diameter, with a ball about $1\frac{1}{2}$ inch at one end, the other end being hermetically closed; the ball contains water, and the empty space is rendered nearly a vacuum by boiling the fluid previously to sealing it. In this instrument the heat of the hand applied to the wetted tube, is sufficient to produce bubbles of vapour, which enter the ball, but speedily collapse. The series of these condensations is as quick as 15 or 16 in a second. But in the steam-engine the condensation is prodigiously more rapid. When a small double steam-engine, on the construction of Boulton and Watt, having all the parts and gear of the large engines, but its cylinder being only $2\frac{1}{2}$ inches diameter, and the length of stroke $6\frac{3}{4}$ inches, was set to work; it gave 600 strokes *per* minute, or about twice as many as the beats of a common watch. By an easy calculation it may be shewn, that the steam condensed was then much more than 300 cubic inches *per* second; and if the condensation, instead of being effected in masses of about a pint at a time, could have been performed by successive collapses of each cubic inch in an open space, the pulses would have produced the tone of the lowest E flat in the treble cliff. But the number of cubic inches condensed in a large steam-engine, *e. g.* a three-foot cylinder with an eight-foot stroke, will be eight or nine times as much at the usual rate of working. See *Nicholson's Journal*, vol. iv. 8vo.

WATER-Level, the level which is formed by the surface of still water, managed in some way or other in a convenient manner for its application in different cases; and which is perhaps the truest of any for most uses. The term is also applied to and signifies the level used in watering land, and performing different other operations in the business of agriculture. See *LEVEL*, *SPIRIT-LEVEL*, and *WATERING Land*.

WATER-Levels are also lengths of canal in some places, that are not connected by locks with other navigations; but at the ends of which the goods are unloaded into team-waggons. See *CANAL*.

WATER-Line and Reel, the strong large line and reel of the garden kind, which is used in forming some part of the works in watering of land.

WATER-Lines, (see *SHIP-Building*), are the lines of floatation supposed to be described by the surface of the water on the bottom of a ship. Of these the most particular are those denominated the *light water-line* and the *load water-line*; the former, namely, the light water-line, being that line which shews the depression of the ship's body in the water when light or unladen, or when first launched, called the *launching draught of water*; and the latter, which exhibits the same when laden with all her guns and ballast, or cargo.

WATER-Logged, in *Sea Language*, denotes the state of a ship when, by receiving a great quantity of water into her hold, by leaking, &c. she has become heavy and inactive upon the sea, so as to yield without resistance to the effort of every wave rushing over her deck. In this dangerous situation of a ship, the crew have no resource, except to free

her by the pumps, or to abandon her by the boats as soon as possible.

WATER, To Make. See *MAKE*.

WATER-Machine. See *MACHINE*.

WATER-Mead or *Meadow*, in *Agriculture*, a term applied to that sort of meadow or other inclosed low ground, which is capable of being improved and kept in a constant state of fertility and productiveness, by means of water from some adjoining river, brook, or stream, being thrown and conducted over it in the winter or other proper season. This manner and beneficial practice of forming meadows has prevailed locally for such a very great length of time in different parts of the country, especially in Wiltshire, Gloucestershire, and Devonshire, that it is extraordinary that it has not been generally adopted and introduced into other districts, where it is equally capable of being had recourse to without great difficulty, and where it may be equally advantageous and proper. This neglect has been ascribed by a late intelligent writer to a deficiency of information among farmers in general, in regard to the nature and management of the business, and particularly in what relates to the nature of levels, and the means of adjusting them in different cases. These circumstances, it is supposed, have confined it to the western districts and parts of the kingdom. Other causes may, however, have operated in this way, as the facilities afforded by the situations of the lands in general, the numerous rivulets and streams always ready at hand for the purpose, and many others of the same nature.

It is necessary that water-meadows should have such a form, either by nature or art, as that this fluid may be capable of flowing over their surfaces in a rapid manner, in order to produce and promote the early and quick growth of the grass in a healthy state. It is essentially necessary, too, to their perfect success and completeness, that there be at all seasons a full command of the water, as well as of the means of distributing it to every part of them, and of discharging it in a complete manner, whenever it may become requisite. See *WATERING Land*.

As to the advantages to be derived from meadows of this kind, they are very considerable, not only in the vastly increased quantities of hay which they afford, but also in the point of early spring food for ewes and lambs, as well as in many other respects and particulars.

It may be observed, that from the grass of water-meadows being so very forward in the months of March and April, it is in general fed down or pastured in the spring with sheep; and to those farmers who keep them for breeding or fattening, becomes almost invaluable, from the great scarcity of green food at such a period; but that after being flooded in the latter end of the last of these months, they are mostly shut up for hay in the summer.

And the after-grass is eaten off in autumn by neat cattle, it being considered as very pernicious and dangerous for sheep to pasture on water-meadows at that season. A remarkable instance of its fatal effects is stated by the writer of the *Corrected Account of the Agriculture of the County of Suffex*. Eighty ewes from Weyhill fair were turned into some field adjoining a watered meadow: a score of them broke into the meadow for a night, and were taken out in the morning, and kept till lambing; when they produced twenty-two lambs, all of which lived, but every one of the ewes died rotten before May-day. The remaining sixty made themselves fat, nor could a rotten sheep be discovered amongst them. It is an extraordinary fact, it is said, though not easily accounted for, that the grass of watered meadows should be so nourishing to sheep in the spring, and yet have so destructive an effect on them in the

autumn. The fact seems, however, to be well and indubitably established. It may probably depend upon the grass being in a more soft and loose watery state of production in the autumn than what it is in the vigorous growth of the spring. See *TATH* and *WATER-Tab*.

By the author of the "*Treatise on Watering Meadows*," it is advised that no sheep, except those that are just fat, should ever be suffered, even for an *hour*, in watered meadows, as they will infallibly rot them at any other season than the spring, but especially if made from low, boggy, or swampy ground; but that it is not so, when made from dry heathy land. Others, however, think it dangerous on all, and therefore always to be avoided.

It cannot be doubted but that on farms of this nature, where it is convenient to have three or four meadows that can be watered, they will be found particularly advantageous; as, while neat stock are eating the first, it is said, the second will be growing, the third becoming dry, and the fourth under water: by which an extensive system of feeding and producing of dry fodder may be carried on.

It is noticed by Mr. Smith, in a late essay on these kinds of meadows, that even a small piece of this sort of meadow, which will produce an early crop of spring feed at the very time of the greatest pressure of scarcity, and when the turnips ought to be off the ground, must be much more valuable to a poor arable farm than can easily be imagined by any one who has not witnessed the great utility derived from them, in many parts of Wiltshire. What, but for the water-meadows, could enable the Wiltshire farmers, it is asked, to bring to market a much greater number of sheep, and that at an earlier season than can be produced from any other county in the kingdom? The water-meadows have unquestionably a great share in doing this.

They afford there, it is said, an early supply of grass for the forward or early breed of lambs, on which they begin to feed them about the middle of March, having previously withdrawn the water from them, and laid them perfectly dry. It is observed, that on a good crop of grass of this kind, it has been said, that five hundred couples may be fed on an acre for one day. The practice is to hurdle out, daily, such a portion of the ground as is necessary, leaving a few open spaces in the hurdles, through which the lambs may feed forward on the fresh grass. The hours they are suffered to feed on this grass, in such cases, are from about ten o'clock in the morning until five in the afternoon, when they are generally folded on the contiguous barley fallows, or lands in preparation for that crop. This is a practice or sort of management, too, which is supposed to have a great advantage, in consequence of its manuring a part of the farm without the dunghill. The manure, however, in such cases, is drawn from, and at the loss of such meadows.

The writer of the *Corrected Report of the Agriculture of the County of Middlesex* mentions a remarkable instance of the beneficial and fertilizing effects of water in these meadows, as occurring in the early part of the autumn of 1796, when such grass lands as had not had the advantages of water, as in these cases, were nearly burnt up. A close of about twenty acres, which had been watered in this way, had, it is said, a most luxuriant after-grass of from six inches to a foot in depth; and a neighbouring inclosure of near forty acres afforded support for three months to forty-seven horses and bullocks, all which thrived very well. And another case of the same nature is recorded, in which forty acres employed in this way were found equal to the support of five hundred Wiltshire ewes, from the middle of the month of March to the first of May, or about six weeks; and

and that the improvement of the stock in that time was one shilling a week, or three pounds fifteen shillings the acre. In some parts of the same county, five pounds worth of hay might also, it is said, be taken off the first week in May. These facts and statements strongly prove and display the utility of these meadows, wherever they can be properly provided.

In speaking of the management of water-meadows, the author of the essay already noticed remarks, that in those great districts of water-meads, which in Wiltshire are watered by the common consent of many different proprietors and occupiers of land, the operation of floating must begin and end at certain fixed periods, which it is necessary for every one to know, and regularly adhere to, not only in order to the production of a crop of grafs, but for the procreation of those animals that eat the grafs: consequently, as every farmer knows at what time he shall have grafs for his sheep, he so manages his breeding flock, that his lambs may be strong enough at the usual time of feeding to go with the ewes to take their food in the meadows, and return to the fold for lodging.

It is noticed, that the time to commence the feeding on the meadows upon those large streams in this county is generally about the twenty-fifth of March: therefore, if the winter be very mild and favourable for the growth of grafs, it sometimes gets to such a height as many farmers, unaccustomed to the herbage, might think to be much too coarse and luxuriant for sheep, and even too high to be fed off with cattle. So great was the luxuriance of the grafs in the water-meads of Wiltshire, it is said, some years since, occasioned by the mild growing weather immediately after the commencement of floating, that some farmers laid their meadows dry, and fed them off in November, and the following month; and then, by floating again, obtained a crop of feed in the spring before the usual period. Many who did not adopt this method lamented that their grafs was too high, even in the month of February; and it was then not uncommon to see it in the water-meads nine inches high, but laid on the ground, and white at the bottom, before the lambs were strong enough to go into the meadows. Some apprehended, it is said, that the long four grafs would be wasted; yet it was astonishing with what avidity the sheep devoured it, and even preferred the parts that were the longest, and rendered white at bottom, in consequence of the extreme thickness: this they would, it is observed, gnaw down to the very roots. It was remarked by Mr. Davis, it is said, that the grafs then on one Rickwood's mead was such a crop as, at the usual time of cutting it, would have been estimated at 18 cwt. *per* acre. Many declared that they never saw the crop of the water-meads so very abundant and early; but on visiting the same meadow, at the particular request of the above-named friend of the writer, on the tenth of March, when it had been in feeding more than three weeks, and asking the floater if they ever began to feed it sooner, he replied that he had had the management of the meadows more than thirty years, and never knew it so early but once, when they began feeding it on the eleventh of the first month in the year. The writer walked over the greatest part of this extraordinary piece of ground with some considerable difficulty, it is observed, from the thickness and height of the grafs; and he could discover but one place, to the great credit of the floater, which was worse than another, and that not two rods square. The man soon saw it noticed, it is said, and before the writer could mention the circumstance, told him he knew what he was looking at, and had contrived to do away even such a trifling defect: so this may be truly said to be, the

writer thinks, a spotless meadow. This shews the nice attention and great care bestowed in forming water-meadows in this district; and in some other counties the care bestowed upon the water-meadows is probably not much, if any less. This would seem to be particularly the case in the county of Gloucester, where very great attention is given to the floating of them, to the manner of feeding them down by live-stock, and the shutting them up for the production of hay, as well as in every other part of their management.

They are there, too, equally valuable and important in the quantity and utility of the produce which they afford, as well as the qualities of it, yielding much profit to individuals, and advantage to the whole district.

The utility and benefit of water-meadows are indeed now beginning to be every where well understood, wherever they are capable of being formed in a convenient and suitable manner.

Water-meadows are in general calculated to afford an early spring feed for sheep, or other sorts of live-stock, which may be continued in feeding by them until towards the beginning of the month of May, when, if designed for the producing of hay, that must then cease; as, if persisted in even for a single week in that month, the hay would, as supposed by some, be wholly ruined in quality, being rendered soft, woolly, and unsubstantial, as in the case of after-math crops: but being then shut up, and floated for some days, a crop of hay is next produced, which is in readiness for the scythe in about six weeks; and this crop being removed, and the meadows again floated as before, a third or after-math crop is afforded, for being pastured by neat cattle and horses, but never, or in few cases, by sheep, or for being used as cut green food in house-feeding, which, in some cases, is probably the most beneficial application of it; as where one or two more such crops are caused and taken in the same way, at the same season.

The great superiority of the produce from water-meadows is thus rendered very evident, and the uses of it not of less value or importance.

Water-meadows should constantly be well eaten down before they are floated, but especially in the autumn.

It is of great advantage, in many different respects, to have separate water-meadows, which can be alternately in the course of feeding off, floating, and being laid dry, as has been already seen; as, by this means, their benefits can never be lost for any length of time. And it is particularly beneficial in providing an uninterrupted succession of after-math pasturage, or of that sort of grafs for being cut and used green in the stalls.

Any thing which is done to the surfaces of water-meadows, in the way of rolling or giving them pressure, should always be done while they are in a quite dry state, about the beginning of the month of March, and never when they are much in a moist condition.

The hay produce of meadows of this sort is mostly proper for all kinds of neat cattle and sheep, but not so suitable for horses, especially those of the working or team kind.

WATER-Measure. Salt, sea-coal, &c. while aboard vessels in the pool, or river, are measured with the corn bushel heaped up; or else five striked pecks are allowed to the bushel. This is called water-measure; and this exceeds Winchester-measure by about three gallons in the bushel.

WATER-Microscope. See MICROSCOPE.

WATER-Mill, in *Rural Economy*, that sort of mill which is turned by the power or force of water applied in some way or other. As mills of this kind often form and oppose great obstructions to different improvements of the farmer,

and especially in the practice of watering land, they should consequently be diminished in number as much as possible in such cases, and those of the tide and wind kinds be substituted in their places, as might be done with great facility in many instances. See *MILL*.

WATER, Mother, in Chemistry. See *CRYSTAL*.

WATER Ordeal, or Trial, was of two kinds; by hot, and by cold water. See *ORDEAL*.

WATER-Organ. See *ORGAN*.

WATER, Petrifying. See *PETRIFYING*.

WATER-Poise. See *HYDROMETER*, and *ARÆOMETER*.

Dr. Hooke has contrived a water-poise, which may be of good service in examining the purity, &c. of water. It consists of a round glass ball, like a bolt-head, about three inches in diameter, with a narrow stem or neck, one twenty-fourth of an inch in diameter; which being poised with red lead, so as to make it but little heavier than pure sweet water, and thus fitted to one end of a fine balance, with a counterpoise at the other; upon the least addition of even $\frac{1}{1000}$ th part of salt to a quantity of water, half an inch of the neck will emerge above the water, more than it did before. *Phil. Trans. N^o 197.*

WATER-Proof Cloth and Leather. It would be very desirable to render the principal articles of clothing impenetrable to water, provided it could be done without injuring the pliability of the cloth.

The most common resource is to line the garment with oiled silk, such as is used for hat-covers and umbrellas; that is, silk which has been dressed with a varnish of drying linseed oil, so as to prevent the admission of water. This effectually guards the wearer of such a garment from becoming wet; but it is not perfect, for the outside cloth can imbibe moisture, which will evaporate by the wind, and cause great part of that coldness which renders wet clothes so prejudicial.

What would be desirable is, that we should give to cloth the same property which we find in the fur of several animals; the otter, beaver, and water-rat. This is a repellence of water, which when thrown upon the animal rolls off in pearl drops, without wetting the fur in the least; but we observe this only in the living animal, and when in a state of health, for these animals are known to be sick when they are found to be wetted after having dived in the water. This perfection has not yet been attained, but we shall proceed to state what has been attempted, with a view of water-proof varnishing for cloth.

Mr. Albert Angel, in 1781, had a patent for preparing an elastic varnish for this and various other purposes. His receipt is, linseed oil, or nut oil, one gallon; bee's-wax (yellow or bleached), one pound; glue or size, six pounds; verdigris, a quarter of a pound; litharge, a quarter of a pound; spring or rain water, two quarts; to be put into an iron kettle, and melted down till it forms the composition.

Caoutchouc, or elastic gum, called Indian rubber, is a substance which has engaged the attention of philosophers, ever since it has been known. Its singular elasticity, its flexibility and impenetrability to water, have caused it to be considered as very valuable for this purpose.

It is not possible to effect the liquefaction of caoutchouc, by means of heat; it will melt as well as other resins, but when cooled, it remains liquid and adhesive. Alcohol or spirit of wine, the usual solvents of resinous substances, do not act upon it, nor is it dissolved in water, as gums are; it was then tried to dissolve it in drying oils, and it was found that by the aid of heat, the caoutchouc may be dissolved, and form an excellent varnish, supple, impervious to air or water, and resisting a long time the action of acids.

VOL. XXXVIII.

With such varnish Messrs. Charles and Roberts covered their air-balloons.

Several essential oils, as those of turpentine and lavender, act upon the caoutchouc, even when cold, and these are of no great price. The disagreeable smell of the oil of turpentine becomes, perhaps in process of time, less disagreeable than that of the lavender.

The oil of turpentine always leaves a kind of stickiness.

The following process is described in a patent granted to Mr. Henry Johnson of London in 1797, for rendering cloth and other articles water-proof.

The article to be operated upon, must first be cleaned from all grease or dirt by washing it with an alkaline solution, and then stretched in a frame. The water-proof compound, as it is termed, is formed by dissolving caoutchouc or Indian rubber in spirit of turpentine, (the smell of which is taken off by adding oil of wormwood, and spirit of wine in equal quantities;) this forms a sort of varnish, which is capable of being spread, or washed over the surface of the leather or cloth, always applying it on the wrong side of the article, or that side which is not to be seen. The varnish is laid on by means of a large piece of Indian rubber, instead of a brush or sponge. To conceal the varnish and make a good internal surface to the cloth or leather, it must be sifted over with some substance, such as silk, wool, or coney, cut very fine, in the same manner as flock paper is made; and being left to dry, in a few days the flock, by its adhesion to the varnish, forms a very good lining, at the same time that it conceals the varnish. These articles were called by the patentee hydrolaines, and were loudly recommended by advertisements, but never came much into use.

M. Pelletier's Method of making Varnish of Caoutchouc, or elastic Gum, by dissolving it in sulphuric Ether.—Boil the elastic gum for the space of an hour in common water, by this it becomes soft enough, to be cut into small threads; being thus divided, put it again into boiling water, and keep the vessel on the fire for about another hour; this second boiling penetrates the elastic gum very sensibly, and deprives it of that hardness which it possesses in the first state.

When the gum is thus divided and softened, put it immediately into a matras, or any other closed vessel, containing rectified sulphuric ether. In the course of a few hours the ether penetrates the elastic gum (which swells very considerably), and at the end of a few days the solution is complete, without the assistance of heat, provided a sufficient quantity of ether is made use of.

According to this process, the solutions are of a white colour and transparent; the heterogeneous and footy particles, which the elastic gum generally contains, fall to the bottom of the vessel in which the solution is made, and have a footy appearance, so that by merely decanting the solution it may be obtained very clear.

Mr. Parrish and Mr. Ackermann have likewise had patents for the same object; the latter succeeded much better than the elastic varnishes.

Water-proof Leather.—In the memoirs of the Academy of Sciences at Turin, 1789, is a paper by the chevalier de St. Real, on the manner of rendering leather impermeable to water, without diminishing its strength or its suppleness, and without sensibly augmenting its price. M. St. Real shews that skins may be tanned in such a way as to give this desirable quality to the leather, and in other respects with benefit to the tanner, by reducing all the processes of the art to the following.

For strong ox or cow leather, which is used for making the outer soles of shoes and boots.

1st, Soak the green hides, separate from each other, in
U running

running water, a sufficient time to extract all the soluble animal matter or lymph; it will be easy to determine when that is done, by putting a piece of the hide into water, and heating the water gradually; if no scum is formed upon the surface, it is a proof that no lymph remains.

2dly, Place the hides (after they have been washed and cleaned) in a cauldron, similar in construction to those in which common falt is made; fill the cauldron with water, which is to be heated to 167 degrees of Fahrenheit, and no more: after the hides have been one hour exposed to this degree of heat, take them out.

3dly, Stretch them upon the horse, and proceed to take off the hair in the usual manner.

4thly, Put them again into the cauldron (which should be so contrived that it may receive as much water from a cock on one side as is let out from a cock on the other side), and so keep up in this cauldron a constant current of water, of the heat of 60 degrees.

5thly, Let the hides remain in this cauldron till the water no longer contains any animal jelly; which may be easily known by evaporating a small quantity of it.

6thly, Take the hides out of the water and place them upon the horse, that the cellular and muscular membrane may be taken off.

7thly, Wash the hides again in running water, then put them again into the cauldron, or one similar to it, which is to be filled with filtered tan-liquor. This liquor is to have the same degree of heat that the water had in the former operation; the skins to remain in it till they are completely tanned, taking care to put fresh tan-liquor in the place of that which shall appear to have lost its energy by the combination of its astringent principle with the hides; this may be readily known by dropping in a few drops of a solution of green vitriol.

The author states, that leather made according to this system would be more free than any other from the animal jelly, which is not combined with the tan, and consequently would be less susceptible of moisture. The fibrous part of the skin being more strongly acted upon by the tan-liquor when heated, would become more firm and more difficult to be penetrated by water; it would be increased in strength and compactness, without losing any part of its suppleness.

That excellent Swedish leather so superior to all other, of which boots, breeches, and great-coats are made, is capable of resisting the most violent rains. This leather is prepared in Jutland with hot water.

In the common way the tanner contents himself, before he delivers the leather to the shoe-maker, with beating those parts which are soft, or which have a very irregular surface, upon a smooth log of wood with a mallet. The more careful tanners beat all their hides; and this practice is general in England.

Besides the strong sole-leather already mentioned, leather of a different kind is used in a great variety of arts and manufactures. It is made of skins of cows and oxen, but more generally of calves'-skins; it serves to make the soles of pumps, or women's shoes; for belts, harnesses, covering trunks, &c. or the inner soles of men's shoes, and the upper-leathers; in short, any kind of work in which the thickest and strongest leather is not required. All this sort of leather is carried, because leather as it comes out of the pits is by no means fit for the various uses for which it is intended: it is rough, of an unequal thickness, and unmanageable. The object of the currier's art is to supple it, and to give it an uniform compactness and density; this object he fulfils by the following operations:

1st, He treads the skins, that is, after having soaked them till they are softened, he kneads them with his feet, to make the water penetrate every part equally.

2dly, He works them with the pummel; this is done by applying to the skins a square tool made of hard wood, about a foot long and five inches broad; it is furrowed longitudinally, and convex at the bottom and flat at top; it is fixed to the workman's hand by a leather strap so that it cannot slip. This tool by being worked forcibly along both sides of the skin, first upon the side of the epidermis, and then on that of the flesh, forms the grain of the leather, and gives it suppleness.

3dly, He then works the skin with an iron instrument with a blunt edge; with this he scrapes very strongly those parts which are too thick, those in which there is left any flesh, or any tan, and those in which there are hollows; driving as it were to press the superfluities of the thick parts into those which are too thin, and thus to give to every part of the skin an equal thickness and an uniform density.

4thly, He pares the skin with a paring-knife; this paring-knife is circular: the workman cuts away those thick and projecting parts which the operation just described was not able to remove; so that this last operation may be considered as completing the object of the preceding one.

After the four operations above-mentioned, the leather is supple and smooth, and of an equal thickness and density in all its parts: it is now in a state capable of being employed by the workmen who make use of it. But the very operations which give it these valuable properties appear to injure its compactness. The leather by being beat, stretched, and scraped, must necessarily become more spongy, and consequently more permeable to water. To remedy this inconvenience, the currier impregnates it with fat or oil.

To dress leather with fat, it must first be made perfectly dry. The pores of the leather are then dilated, by passing it over a clear strong fire, and it is rubbed over with a kind of woollen mop dipped in melted fat, pretty hot. The fat thus applied to each side of the leather penetrates into its substance, lodges within its pores, and adhering there fills them up so as to preclude the entrance of any moisture; should the leather be wet when the fat is applied, it will remain upon the surface, and not penetrate into the substance.

The manner of dressing leather with oil is the reverse of this, and is founded upon the property which water possesses of swelling those supple and elastic capillary tubes into which it insinuates itself; also that of its not being miscible with oil, and upon that of its evaporating much more speedily than oil.

The currier therefore soaks those skins in water which he means to dress with oil, and while they are yet wet, he spreads over them with a wool mop any kind of fish oil. As the water evaporates, the oil takes its place; and consequently the more the skins were swelled with water, the more thoroughly they become impregnated with oil.

M. St. Real found the cow-leather dressed with fat imbibes more water than the calf-skin dressed with oil; but he attributes this difference to the manner in which the currier applies the fat. He rubs the leather with a kind of mop, dipped into melted fat moderately warm, it seems impossible that, by this manner of applying it, the fat can penetrate into the interior parts of the leather; the air contained in its pores opposes an invincible obstacle to the penetration of it. On the contrary, there is no air in the pores of the wet leather upon which the oil is applied, and the permanent fluidity

WATER-PROOF.

fluidity of the oil itself also facilitates its passage into the leather.

To make the leather imbibe the fat, he proposes three or four days immersion in running water, to drive out the air; then to soak the leather in melted fat, of the temperature of 167 degrees of Fahrenheit, till all the water in the leather is evaporated by the heat; the fat would then penetrate into the interior pores of the leather, and render it impermeable to water.

If leather is compressed, it evidently diminishes the thickness, and increases its compactness; and if it is beaten with an iron hammer upon a very smooth anvil, it produces a permanent contraction of its pores. Leather is in that respect very much like iron, and all other metals which harden by beating; and, consequently, our author suggests that it would be of great advantage to compress the leather before it is used, by passing it between a pair of rollers, such as are used to flatten metal: this would stiffen the leather.

It appears from experiment that the strong sole-leather, by being properly impregnated with fat, and compressed in the rollers, absorbs only one-thirteenth part of water, imbibed by the same leather which has not undergone those operations. The quantity of water which the first absorbs, and which amounts to about one-thirtieth part of its weight, is so small, that it does not render it capable of wetting any substance it may come in contact with, nor does the leather appear wet when taken out of the water; it may therefore be considered as almost impermeable to it.

The cow-leather, when impregnated with fat, and compressed, absorbs about one-ninth part of the water absorbed by leather of the same nature which has not undergone those operations. The quantity of water absorbed by the first amounts only to the thirty-fourth part of its own weight.

The calf-skin, when impregnated with fat and compressed, absorbs only one-third part the quantity of water that the same quantity of leather absorbs when it has not undergone those operations; and that quantity is not so much as one-fortieth part of the weight of the leather.

In this manner, without making any alteration in the usual method of tanning, except with respect to the thin sole-leather, it is possible to render leather very nearly impermeable to water, by the known operations of currying, provided to them are added compression by rollers, and soaking in fat, as before described. The additional greasing and pressing will not sensibly increase the price of the leather, for it retains only about the sixteenth part of its weight of fat.

The leather which had passed through the rollers was not diminished in its strength; for it supported, without breaking, weights as heavy as were supported by leather of the same kind which had not undergone that operation.

In 1794 Mr. Bellamy of London obtained a patent for a method of rendering leather water-proof, which he thus describes.

Take nut oil, one gallon; poppy-oil, one gallon; and linseed-oil, two gallons; or they may be in other proportions: put them into an iron vessel, and set it over a gentle fire. To every gallon of the mixed oils, put half a pound of amber, or white copperas, sugar of lead, colcothar, or any other proper drier, but observing to use a larger proportion than the above, when the oil is to be prepared for new leather, or a lesser proportion when it is to be prepared for old.

Let the oils remain on the fire, and give it as great a degree of heat as it can bear without burning, or causing it to

rife, for six or seven hours; and if it will not dry sufficiently continue the same degree of heat till it does: then take it off the fire, and when it is a little cooled, it is ready to be applied to make water proof leather.

This is done by a brush being dipped into the prepared matter, and rubbed or brushed into the leather.

When the article is well filled with the prepared oils, lay it on an even board, and scrape off what is superfluous with a thin iron tool; then put it to dry in a warm room, and when sufficiently dry it will be fit for use.

For sole-leather of thick substance, let it be gently warmed, and with a brush or pad, made of wool or hair, rub or brush the prepared matter on the leather, till it is thoroughly saturated; then let it dry in a warm place, and it is ready for use.

The proportion of the mixtures of oils, must be varied according to the nature of the oil, and also according to the nature of the leather, for the same kind of oil will not always have the same qualities.

Oils expressed at different times will frequently have a greater or less propensity to finish; and must, on that account, have more or less of the poppy or nut oils. If the drying oil finishes reluctantly, there must be added a lesser quantity, or none at all, of the nut or poppy oils, and a small quantity of an essential oil added, till it will finish with ease and beauty. The same kind of leather will also require a different mode of treatment; for if the leather be new it will abound more with the natural grease of the animal which produced it, and it will require the oil to be so managed as to absorb or neutralize the greasy quality, that it may finish without loading the leather, and making it unpleasant to the wearer. When this is the case, one-fourth part of essential oil of turpentine must be mixed with the above oils when prepared; and *vice versa* if the leather is old.

Another of Mr. Bellamy's receipts is as follows: to one gallon of the above prepared oils add one pound of gum resin, half a pound of pitch, a quarter of a pound of tar, and a quarter of a pound of turpentine. Let them be well incorporated with the oils, by first heating the whole mass gently, and then increase the fire till the whole is thoroughly mixed; or he proposes to add to the oils, gums sandarach, mastic, anime, copal, amber, together or separate, or asphaltum, or one-sixth part of bee's-wax. In short, any bituminous, resinous, or adhesive matter, which will resist acids, alkalies, and water, and will unite with drying oils, provided when mixed in proper proportions they do not render the leather hard, or make it crack, or otherwise disagreeable.

In the *Annales de Chemie*, Mr. Hildebrand of St. Peterburgh proposes the three following methods of rendering sole-leather impermeable by water.

The first preparation is made by boiling $1\frac{1}{2}$ lb. of minium with 20 lbs. of oil of linseed, or hemp-feed; continue the boiling till the metallic oxyd be entirely dissolved, and the mixture assumes a carbonaceous dark brown colour: apply this composition to the inside of the hides till they can absorb no more of it; then dry them, in summer by the heat of the sun, in winter before a fire. When the composition becomes too thick, it may be liquified by the addition of oil of turpentine.

The second preparation is simply either of the same oils, in part dishydrogenated by fire; it will serve equally well for upper leathers.

The third preparation is a mixture of two ounces of black pitch with a pound of tar, melted together by a gentle heat;

the leather is then anointed with the mixture, and dried. Soles thus prepared ought to be used with the smooth side inwards.

Another receipt for an elastic water-proof varnish is, gum asphaltum, two pounds; amber, half a pound; gum benzoin, six ounces; linseed-oil, two pounds; spirits of turpentine, eight pounds; and lamp-black, half a pound; united together in an earthen vessel over a gentle fire.

The leather is to be nailed on a board, and the varnish applied upon it; it is then to be passed into an oven several times, the varnishing being each time repeated, till the leather is completely covered.

Mr. William Baynham took a patent in 1816 for a water-proof varnish, which very much resembles those of his predecessors. It is prepared as follows: six gallons of linseed oil, one pound and a half of rosin, and four pounds and a half of red litharge, or any other substance usually known under the denomination of dryers, are to be boiled together till they acquire sufficient consistence to adhere to the fingers, and draw out into strings when cooled upon a piece of glass or otherwise. It is then to be removed from the fire, and when sufficiently cooled, thinned to about the consistence of sweet oil, by adding spirits of turpentine to it, which generally requires about six gallons. It is left to settle for a day or two, and then carefully poured off from the grounds; and about one pound and a half of ivory or lamp-black, and one pound and a half of Prussian blue ground in linseed oil, added to and intimately mixed with it. It is then ready for use.

To apply this varnish, stir it up, and lay it on with a brush until it lies on the surface of the leather with an even gloss; then hang up the article which has been operated upon until the next day: repeat the application as before, taking care to leave the surface as thin and even as possible. This must be repeated each successive day, until it has the desired appearance.

WATER, Raising, in Rural Economy. See RAIT.

WATER-Rocket. See ROCKET.

WATER-Sail, in a Ship, denotes a small sail, spread occasionally under the lower studding-sail, or driver-boom, in a fair wind, and smooth sea.

WATER-Scape, of the Saxon waterschap, denotes an aqueduct, drain, or passage for water.

WATER-Shield. See HYDRASPI.

WATER-Shoot, a young sprig, which springs out of the root or stock of a tree.

WATER-Shot, in Sea Language. See MOORING.

WATER-Spout. See WATER-SPOUT.

WATER-Table, in Architecture, is a sort of ledge, left in stone or brick walls, about eighteen or twenty inches from the ground; from which place the thickness of the wall begins to abate. See WALL.

WATER-Thermometer, a thermometer made with water by Mr. Dalton, for the purpose of ascertaining the precise degree of cold at which water ceases to be farther condensed; and likewise how much it expands in cooling below that degree to the temperature of freezing, or 32° . With this view he took a thermometer tube, such as would have given a scale of ten inches with mercury from 32° to 212° , and filled it with pure water. He then graduated it by an accurate mercurial thermometer, putting them together in a basin filled with water of various degrees of heat, and stirring it occasionally: as it is well known that water does not expand in proportion to its heat, it does not therefore afford a thermometric scale of equal parts, like quicksilver.

From repeated trials agreeing in the result, he found that

the water-thermometer is at the lowest point of the scale it is capable of, that is, water is of the greatest density at $42\frac{1}{2}^{\circ}$ of the mercurial thermometer. From 41° to 44° inclusively, the variation is so small as to be just perceptible on the scale; but above or below those degrees, the expansion has an increasing ratio, and at 32° it amounts to $\frac{1}{8}$ th of an inch, or about $\frac{1}{16}$ th part of the whole expansion, from $42\frac{1}{2}^{\circ}$ to 212° , or boiling heat. During the investigation of this subject, his attention was arrested by the circumstance, that the expansion of water was the same for any number of degrees from the point of greatest condensation, no matter whether above or below it: thus he found that 32° , which are $10\frac{1}{2}^{\circ}$ below the point of greatest density, agreed exactly with 53° , which are $10\frac{1}{2}^{\circ}$ above the said point; and so did all the intermediate degrees on both sides. Consequently, when the water-thermometer stood at 53° , it was impossible to say, without a knowledge of other circumstances, whether its temperature was really 53° or 32° . Our ingenious author, recollecting some experiments of Dr. Blagden in the Philosophical Transactions, from which it appears that water was cooled down to 21° or 22° without freezing, was curious to see how far this law of expansion would continue below the freezing point, previously to the congelation of the water, and therefore ventured to put his water-thermometer into a mixture of snow and salt, about 25° below the freezing point, expecting the bulb to be burst when the sudden congelation took place. After taking it out of a mixture of snow and water, where it stood at 32° , (that is, 53° per scale,) he immersed it into the cold mixture, when it rose, at first slowly, but increasing in velocity, it passed 60° , 70° , and was going up towards 80° , when he took it out to see if there was any ice in the bulb; but it remained perfectly transparent: he immersed it again, and raised it 75° per scale, when in an instant it darted up to 128° , and that moment taking it out, the bulb appeared white and opaque, the water within being frozen: fortunately it was not burst; and the liquid which was raised thus to the top of the scale was not thrown out, though the tube was unsealed. Upon applying the hand, the ice was melted, and the liquid resumed its station. This experiment was repeated and varied, at the expence of several thermometer bulbs, and it appeared that water may be cooled down in such circumstances, not only to 21° , but 5° or 6° , without freezing; and that the law of expansion above-mentioned obtains in every part of the scale from $42\frac{1}{2}^{\circ}$ to 10° , or below, so that the density of water at 10° is equal to the density at 75° .

WATER-Tight, in Sea-Language, the state of a ship when not leaky.

WATER-Tracing Crescent, in Rural Economy, the tool formed in the manner of the gardener's edging-iron, but made much larger, and in the crescent form, very thin and well-steeled, and sharp in the edge, having a stem about three feet in length, with a cross handle for bearing upon in working with it, in cutting out the sides of the different conductors of the water in watering land. See WATERING Land.

WATER-Ways, in Ship-Building, the side-strake of a deck wrought next the timbers, and much thicker than the deck, but reduced to the thickness of the deck in front: it makes a channel for the water to run through the scuppers, and prevent leaking at the side.

WATER-Wheel, an engine for raising water in great quantity out of a deep well. See PERSIAN-Wheel, and WATER, Raising of, supra.

WATER-Workers, in Agriculture, a term applied to the makers and formers of meadow-drains and trenches, or wet ditches.

ditches, as in the practices of watering and draining of land, or otherwise.

WATER-Worm, *Reproduction of*, in *Natural History*. See *REPRODUCTION*, and *Water-Worm*. See also *VERMES*.

WATER Key, in *Geography*, a small island in the bay of Honduras, near the coast of Mexico. N. lat. $17^{\circ} 30'$. W. long. $88^{\circ} 40'$.

WATER Key, a small island in the Spanish Main, near the Mosquito shore. N. lat. $12^{\circ} 15'$. W. long. $82^{\circ} 55'$.

WATER Key, South, a small island in the bay of Honduras. N. lat. $16^{\circ} 35'$. W. long. $88^{\circ} 45'$.

WATER Point, a cape on the east coast of Java. S. lat. $7^{\circ} 55'$. E. long. $114^{\circ} 33'$.

WATER Sound, a strait of the North sea, between South Ronaldsha and Barra, two of the Orkney islands.

WATERBOROUGH, a town in the district of Maine, and county of York, containing 1395 inhabitants; 15 miles N.W. of Wells.

WATERBURY, a town of the state of Connecticut, containing 2874 inhabitants; 20 miles S.W. of Hartford.

WATEREE, a river which rises in the Allegany Mountains, then runs southerly into South Carolina, and changing its name to Wateree; after a course of about 120 miles, it joins the Cangaree, and then takes the name of Santee.

WATERFORD, a maritime county of Ireland, in the province of Munster, having the county of Cork on the west, the counties of Tipperary and Kilkenny on the north, the county of Wexford on the east, and St. George's Channel on the south. It extends from east to west 40 Irish, or 51 English miles; and from north to south 23 Irish, or 29 English miles. Its breadth, however, varies much, and is in one part not more than six miles. The area is stated to be 262,800 acres, or 410 square miles Irish, which are equal to 425,692 acres, or 665 square miles English. Dr. Beaufort states the number of houses to be 18,796; and the number of inhabitants at least 110,000. The number of parishes is 74, in which there were 21 churches, divided between the sees of Waterford and Lismore. Waterford returns four members to the imperial parliament, two for the county, one for the city of Waterford, and one for the borough of Dungarvan. The county of Waterford is in general hilly, and the northern part is particularly rough and mountainous; in the south and east the soil is rich and productive. In the west of the county, on the north of the Blackwater, there is a ridge called the *Knockmeledown* mountains, many parts of which are very high, though Mr. Twiss is mistaken in calling them the highest in Ireland. The Comeragh mountains cover a great extent of country between Dungarvan and Clonmell. These hills, except in a few desolate and craggy spots, afford pasture to small cows, which produce a great quantity of butter. In the eastern part agriculture has been much improved, and the farms are not surpassed in any part of Ireland.

The river Blackwater flows through the west of this county into the bay of Youghal, and is navigable to Cappoquin. The banks of this river are peculiarly beautiful, especially near Lismore. The river Bride, which joins the Blackwater, passes near the town of Tallow, and is so far navigable for large boats. The gentle and majestic Suir forms the northern boundary, dividing it from the counties of Tipperary and Kilkenny, and running east till joined by the Barrow; when, turning south, they form an estuary, 9 miles long, and 2 broad, which is the harbour of Waterford. At Dunmore, near the extremity of this, on the Waterford side, a very fine pier is building, for the protection of the packets, and of such vessels as may put into this harbour.

Dr. Charles Smith published "The ancient and present State of the County and City of Waterford," in the year 1745, which was reprinted in 1772. In this work, he states the Menapii to have been inhabitants of this county and Wexford in the time of Ptolemy, which Menapii he supposes to have been a colony from the Belgic Menapii, mentioned by Cæsar. The Desii are stated to have been a powerful clan at the time of the English invasion. These came from the county of Meath, and gave name to the baronies of Desies within and Desies without Drum, and their descendants are now called Deasy. Though the power of the Desii was abolished by the English, yet, for many years after, the O'Feolains, kings of the Desii, are occasionally mentioned in the Irish annals. Henry II. in 1177 made a grant of the city of Waterford, with all the circumjacent province, to Robert Le Poer, his marshal, from whom are descended not only the family of Le Poer, the head of which was created, in 1535, earl of Tyrone, but also the several respectable families of Power, settled at Clashmore, Gurteen, &c. By marriage, the estates and honours of the Le Poers came to the family of Beresford, the head of which is now marquis of Waterford, and has a noble seat at Curraghmore, in this county. In the civil war, Waterford had its share of disturbance, and Cromwell himself was engaged unsuccessfully in the siege of its capital. Dr. Smith's Topography is still interesting to the reader, from the various information he collected respecting the different families settled, though many of them are now extinct or removed. His natural history is very defective, yet it is the best hitherto published. He drew attention to the fisheries, and to the Nymph bank, yet even now, though employment is so much wanted, the fisheries remain without encouragement. In his enumeration of eminent men born in this county, we find the names of Congreve the poet, and of Robert Boyle, who was born in the castle of Lismore. The duke of Devonshire, as descendant of the eldest branch of the Boyle family, possesses the towns of Dungarvan, Lismore, and Tallow, with a great tract of land, which gives him a preponderating influence in the county. Beaufort's Memoir of Ireland, &c.

WATERFORD, a city and sea-port town on the south side of the river Suir, in Ireland, capital of the county of the same name. This river is embanked by a noble quay, extending the whole length of the town, to which vessels of great burden can come up, though the largest ships generally lie a few miles lower down. Like most of the other sea-ports of Ireland, it was originally built by the Ostmen or Danes; and is said to have been founded A.D. 853, nearly at the same time as Dublin and Limerick. Waterford seems to have been the chief settlement of this people, for we find the kings of the Danes of Waterford often mentioned in the old annals. Strongbow, soon after his landing in Ireland, took Waterford by assault in 1171, and in 1172 he gave it up to king Henry II., who landed at Waterford, and received there the submission, not only of his English subjects, but also of many Irish chiefs. King John also landed at this city, and made it his residence for some months. The steady adherence of Waterford to the English caused it to be engaged in almost constant warfare with its neighbours; and in return it received many marks of royal favour. Richard II. landed twice at Waterford. When Simnel was crowned king by the earl of Kildare, the lord deputy, the citizens of Waterford refused to admit him, adhering steadily to Henry VII., in consequence of which he addressed a letter to them, thanking them for their adherence, and giving them power to seize the rebels and their effects, and to employ the latter for their own advantage. They behaved with the same loyalty against Perkin

Warbeck,

Warbeck, who had many adherents in Ireland, in consequence of which the king gave them this motto, which is still used, "Intacta manet Waterfordia." In the reign of James I., Waterford appears to have become turbulent in consequence of its attachment to the Roman Catholic religion, and in consequence was deprived of many privileges, but these were restored by Charles I. In the civil war, Waterford was on the side of the Catholics, and a meeting of the popish clergy was held there by the pope's nuncio in 1646. It was besieged by Cromwell without success; but was afterwards taken by Ireton. It has been already mentioned that Waterford was built by the Danes; it was at first called *Portlargo*, from *laarge*, a thigh; the course of the river Suir, near this place, resembling that part of the human body. The English gave it its present name, as it is said, from a ford in St. John's river, which empties itself into the Suir. The city chiefly faces the north and east, which, though seemingly a situation not so desirable, being exposed to the chilling blasts of these winds, yet the healthiness of it makes amends for the bleakness of the exposure. A further advantage is its noble situation, near the confluence of three large and navigable rivers, the Suir, the Nore, and the Barrow, by which inland commodities may be supplied at a very inconsiderable expence of carriage, from the very centre of the island, and from seven different counties washed by these rivers, and other counties adjacent to them. Over the river Suir, a fine wooden bridge has been erected within a few years, to facilitate the communication with other places. A very flourishing commerce with England and other countries is the happy consequence of such a situation. Its exports of beef, butter, hides, tallow, pork, and corn, are considerable. The number of large hogs weekly slaughtered during the season exceeds 3000 on an average. The quantity of butter annually exported exceeds 80,000 casks.

This city is also largely concerned in the Newfoundland trade. The population is supposed to exceed 40,000, and it ranks as the fourth town of Ireland in extent, and the fifth in commercial importance. Packet-boats are established between this port and Milford Haven, for the convenient intercourse of the south of Ireland with England. This city sends one member to the united parliament, elected by the freemen and freeholders. This election is free, and, to the honour of the electors, sir John Newport, one of the most steady friends of Ireland, has been repeatedly returned. The cathedral of Waterford, adorned with an elegant steeple, is a fine structure. There is also a very superb Catholic chapel, with several other places of worship. The other public edifices are constructed with much elegance, and essentially contribute to ornament the city. It is, however, of more consequence to observe, that its numerous charitable institutions are well conducted, and liberally supported. Its house of industry may serve as a model for others. Its fever hospital was the first in Ireland, and nearly the first in the united kingdom, and has been carried on with uniform success. Without any wish to take from the merit of other worthy individuals, much of this praise is due to the exertions of the *Society of Friends*, who are numerous in Waterford. This city is $74\frac{1}{2}$ Irish miles S.S.W. from Dublin. Smith's Waterford. Carlisle's Dictionary. Wakefield, &c.

WATERFORD and **LISMORE**, *Bishopric of*. The first of these sees, which is confined to the eastern part of the county of Waterford, and is very small, was founded by the O'ftmen in the 11th century; but that of Lismore, which includes the greatest part of Waterford county, and a considerable portion of Tipperary, was founded in the seventh

century. The union took place in 1536. The extent of the union is, in Irish miles, 39 by 29, and in English 49 by 37. The number of Irish acres 354,800, which are divided into 106 parishes. Forty-four of these are inappropriate, and the rest form only 44 benefices, of which, when Dr. Beaufort published his account, only 30 had churches, and only 8 glebe-houses. Many churches and glebe-houses have been built throughout Ireland within a few years. Beaufort.

WATERFORD, a populous and compact incorporated post-village, in the S.E. corner of Half Moon, Saratoga county, on the W. bank of the Hudson; 10 miles N. of Albany. It is the most populous town in the county, and has the greatest share of trade. It is handsomely laid out, in 5 E. and W. streets, intersecting at right angles. It has 190 houses and stores, 2 houses of worship, and some other buildings, together with three schools on the Lancaster plain. It is well situated for a manufacturing town; and in 1812 a wharf, 320 yards long, was constructed, and a canal along it to the channel of the Hudson.

WATERFORD, a town of the state of Vermont, in the county of Caledonia, on the W. bank of the Connecticut, formerly called Littleton, containing 1289 inhabitants; 40 miles N. of Norwich.

WATERFORD, a post-town in the district of Maine, and county of Oxford, containing 188 inhabitants; 95 miles N. of York.

WATERFORD, a post-town of Virginia; 20 miles N.W. of Washington.

WATERFORD, a town of Connecticut, in the county of New London; containing 2185 inhabitants.

WATERFORD, or *Le Beuf*, a post-town of the state of Pennsylvania, in the county of Erie, containing 162 inhabitants; 370 miles N.W. of Washington.

WATERFORD, a township of New Jersey, in Gloucester county, containing 2105 inhabitants; 40 miles S. of Trenton.—Also, a town of Ohio, in the county of Washington, containing 701 inhabitants.

WATERGUCHEE, or **WATERQUECHIE**, a river of Vermont, which runs into the Connecticut, N. lat. $43^{\circ} 34'$. W. long. $72^{\circ} 18'$.

WATERING, in *Gardening*, the practice or means of rendering seeds, plants, shrubs, and trees, as well as garden-grounds, properly and suitably moist for the purpose of their better, more ready, and more healthy germination, growth, and taking root, when sown, planted out, or set, and afterwards for continuing them in the necessary states of vegetation, growth, and increase, especially when the weather is dry, hot, and parching. It is also occasionally useful in preventing some sorts of fruit-trees from being destroyed by the attacks of different sorts of insects, as well as for the clearing them of other kinds. It is occasionally equally essential for the seeds and plants in the full ground, as for those in pots in it, and those in green-houses, glass-cases, hot-beds, hot-houses, stoves, and other similar situations; such, for instance, in the former kinds, as the seeds in drills, beds, and other open places, different young plants in the same situations, numerous others of the cutting, slip, offset, and other similar kinds, which have been newly pricked out, planted, or transplanted, not only at the time of first putting them out, but now and then afterwards, when dry hot weather is present; also in many kinds of newly-planted young trees and shrubs in the spring and early autumnal plantings; and to all the plants which are in pots in the open air, whether they may be of the more or less hardy kinds, during the droughty seasons of spring, summer, and early autumn; and in the latter description, to all the fine tender kinds

kinds of potted plants and trees under any sort of covering or protection of the house or other kind.

There are many sorts of plants which cannot exist without watering in either a small or plentiful manner. Some stand in need of it only in a slight degree, and at particular seasons of the year, while others demand it in very full proportions at all times. Some are very nice in the quantities which are required at any one time; but others are less particular in this respect. Some too are under the necessity of having it thrown over their leaves as well as to their roots; others only have occasion for it to the root part. And there are some other methods of administering and applying it, which are peculiar to certain kinds of plants, trees, and other vegetable products, as shewn under their particular individual modes of culture.

In all cases, the most proper water for this use is that which is contained in any sort of pond, reservoir, or other similar kind of excavation, for the purpose of containing it in a state of constant exposure to the atmosphere, in gardens or other places, as it is not only more convenient and ready for being employed, but, at the same time, a great deal more salutary, and better adapted to promote the growth and increase of the different sorts of plants and vegetables, than that of the raw, sharp, cold, hard kind, which is drawn from wells or raised by pumps for immediate use, as being more soft in its nature, and more suitable in its temperature.

The most suitable time of applying it is in the evening, after the disappearance of the sun, and when the excessive heat of the day is gone off, and in a great measure abated, as its effects are then more beneficial and lasting; and besides the work can be performed with more ease and convenience, as well as in a more agreeable manner.

When once the business of watering has been commenced, it should always be regularly proceeded with, or the plants or vegetables may suffer much, and be greatly injured by the omission or neglect. It is constantly better never to attempt it, than to just begin and then leave it off again, as is much too frequently the case, in the practice of horticulture, with some gardeners, who have not fully considered the matter.

The work of watering seeds, plants, shrubs, and trees, is usually performed, either by means of common watering pots and cans, large syringes contrived for the purpose, forcing engines for throwing it up over the plants, or by some other contrivance of a similar nature. The water being mostly brought to the places where it is wanted, either in tubs hung in a sort of barrow-frame, or by their being placed on the barrows themselves.

The water is commonly applied in a fine divided state, over the plants, where it is not required in any large quantities, and for clearing away and destroying smuts: but where it is demanded in large proportions, it is often poured in full streams to their roots or other parts.

But in using it upon a large scale for garden-grounds, Mr. London has suggested that it may be accomplished by a practice somewhat similar to that of overflowing tillage-land, or by means of subflooding; this last may, he thinks, be effected by having a stratum or layer of gravel underneath the whole garden, which by having a trench surround it, or, if upon a slope, at the upper side of it only, may have the ground wholly saturated with the water let into it, which will soon be absorbed and taken up by the incumbent surface containing the vegetables that are under cultivation. And, in the former of these methods, by having pipes, open-cuts, or rather small wooden troughs, which may serve to convey and conduct the water upon the surface of every

quarter of the ground; it may there distribute itself in the intervals between the beds or drills, as well as over the general surface of the broad-cast crops. It is further suggested that the former method could be put in practice at any period of the spring or summer; the latter, for the most part, in moist weather, or in the night season. See *WATERING of Land*.

In the watering of both seeds, plants, and garden grounds, much care should, however, be taken, in every instance, that injury instead of good be not done, by employing too large quantities, or continuing them for too great a length of time.

On the whole, it will be evident, from what has been said above, that the practice of watering in garden culture may be beneficial in different ways, as in exciting and promoting a better and more speedy vegetation in newly-sown seeds and transplanted vegetables; in forwarding the growth and increase in a proper manner of different crops, plants, and trees; and in the destruction or removal of insects, such as the *aphis*, red spider, and some of the *coccus* tribe.

WATERING-Barrow, in *Gardening*, such as is employed in conveying water to gardens or other places. They have usually a tub fixed upright in the frame by means of pivots, hooks, and gudgeons, or some other way, one-half of which is below and the other above it, the water being, in a great measure, prevented from spilling while it is carrying. See *QUENDON Water-Barrow*.

WATERING Forcing-Engine, an engine contrived for the purpose of forcing water in a sort of shower over some kinds of fruit-trees, garden vegetables, and plants, and which commonly effects the business in an easy, convenient, and effectual even manner, being well adapted to particular modes and purposes of watering.

WATERING of Land, in *Agriculture*, the practice of overflowing it artificially in the grass state, with the water which is diverted from an adjoining or neighbouring river or stream, which has a higher level than the ground to be covered, or where there is a proper fall. In this way, by the new-formed water-courses being kept nearly on the level, the spaces of land between the new and the old channels may be watered, the water being brought upon the ground by the former, and discharged or taken away by the latter; and thus a constant succession of the water be retained and removed without such an accumulation of it as would be injurious, or such a deficiency as would leave any part imperfectly supplied. In different districts different names are applied to this practice, such as those of floating, flooding, drowning, foaking, and some others.

It is, without doubt, a practice of great antiquity, which it is probable the extraordinary fertility afforded by the annual overflowings of the river Nile, in Egypt, may have first suggested as the means of improving the lands of other countries. In this country, indeed, it would seem to have been had recourse to, for the purpose, at a very early period, as in the county of Hereford, it appears to have been practised more than two hundred years ago, as is evident from a work on the subject written by Rowland Vaughan, and published in the year 1610, entitled "Most improved and long-experienced Water-Works; containing the manner of summer and winter drowning of meadow and pasture, by the advantage of the least river, brook, fount, or water-mill adjacent; thereby to make those grounds, especially if they be dry, more fertile ten for one." And the practice is probably still more ancient in the county of Wilts than in the above or any other district, in consequence of its possessing naturally watered grass lands, which perhaps first led

to the notion of forming them in an artificial manner. The general want of good pasture-grounds in the high lands of this county might, it has been supposed, be a great inducement to improve such watery valley-tracks, which must ever have displayed the most pleasing and interesting appearances of early and luxuriant vegetation and growth.

However, in whatever way the practice originated in this country, it is unquestionably a method that is deserving of the attention of the land proprietor and the farmer in a very high degree.

It has been stated by different writers on the practice of watering land, that the most proper qualities of the grounds for being watered, are all those which are of a sandy or gravelly friable open nature, as on such the improvement is not only immediate, but the effects produced more certain and powerful than on other kinds of them. There are also some strong adhesive four wet lands, which are also capable of being improved by watering.

There are still some other sorts of lands, as those which contain different kinds of coarse vegetable productions upon their surfaces, such as heath, ling, rushes, boggy and other aquatic plants, which may likewise be much improved by watering. It should, however, be constantly kept in mind, in attempting this sort of improvement, that the more stiff and tenacious the soil or land is, the greater the command of water should be, in order to effect the purpose.

The lands which admit of this sort of improvement with the most success and benefit are, for the most part, all such as lie in low situations on the banks and borders of brooks, rivers, and streams, or in sloping directions on the sides of hills, to which water can be conducted in an easy and ready manner.

The writer of a late useful tract on the subject, however, seems inclined to suppose that there are only a few soils or sorts of land to which watering may not be advantageously applied; the experience which he has had, it is said, has determined, that the wettest land may be greatly improved by it, and likewise that it is equally beneficial to that which is dry. But that as many persons, unacquainted with the nature of watering land, may be more inclined to the latter supposition than the former, the reason of wet land being as capable of improvement by watering as that which is completely dry before it is used, is explained. It is that, in the construction of all watered meadows or lands, particular care must be taken to render them perfectly dry when the business of floating or covering them with water shall terminate; and that the season for floating or watering is in the winter and not in the summer, which those who are unacquainted with the process have too commonly supposed. All bogs of the peat kind are certainly, it is said, of vegetable origin, and those vegetables are all aquatic in their nature. It therefore follows that the same water which has produced the vegetables of the bog would, under due management upon the surface, produce such grasses or other vegetables as are usually grown by the farmer; and the writer has hitherto had reason to think, that this may be considered as a general rule for determining the situation for any experiments or trials with water. The writer having succeeded in the attempt to make good watered lands, upon soils which have been thought unfit for the purpose, and floated or watered them with water that was equally condemned, in point of quality, he is now, it is said, sufficiently emboldened to recommend the trial of watering land by means of machinery, and that the most flattering hopes of success are entertained from it. It is noticed that the grasses produced by the first year's floating or watering of a peat-bog, or any wet land, will be much more like what

will become the permanent herbage of a water-meadow, than the first or second year's crop from a newly-floated or watered piece of dry land. The herbage of the former being, it is said, previously stored with aqueous plants, is in some degree suited to this new state, whereas the herbage of dry land is generally of quite a different nature, and often produces an exceeding great crop of grass the first year, which does not appear the next; for the same water which caused these grasses to grow so very luxuriantly the first year, will totally destroy them in the course of the ensuing winter, and produce an herbage much more congenial to that degree or state of moisture. The utility of watering in all these cases has been fully established in several different districts, so that proper examples of the forms and crops may always be readily had for the trials of others in the same way. This has been done, it is said, in the counties of Bedford, Norfolk, and Kent, in the first and last of which upon soils that are very different from those of most water-meadows in the county of Wilts; and that the floating or watering of them has been effected with water which was always before considered to be wholly unfit for that purpose, even by those supposed to be the best acquainted with the practice: it is now, however, fully proved and shewn to be the case, not only by the accurate investigations of the most able chemists, but by the extraordinary growth of grasses in particular boggy situations, that waters of the ferruginous kind are not at all hurtful to vegetation; but, on the contrary, very friendly to it, when they are properly applied. Such facts being established beyond all possibility of doubt, afford, it is said, a much greater scope for the improvements by water, than was ever expected or thought of by the most sanguine advocates of watering, and enables the writer, from his great experience and observation, in different parts of the kingdom, to say that there are few districts to which they are not applicable.

It is, however, supposed by some, that the quality of the water, like that of marl or other manures, is a matter of the first importance, and should be particularly ascertained. And it has been remarked by the author of the "Treatise on Landed Property," that it is universally known that water which flows out of a dung-yard possesses a fertilizing quality. It is generally admitted, too, that the washings of sheep-walks, freshly-manured arable lands, streets of towns, roads, and other such places, after a long drought, have the quality of fertilization. And it is equally evident, it is thought, that the waters issuing in different parts of the kingdom from chalk, lime-stone, marl, or other calcareous stratum, though they are perfectly limpid, possess the power of fertility; and those of some districts, as of Wiltshire, Dorsetshire, and some others, to an astonishing degree. And a similar, though less powerful, effect is produced by the limpid waters, which issue from the slate-rocks of Devonshire and Cornwall. On the other hand, waters that ooze out of peat-bogs, and issue from particular mines, are well known to be injurious to the growth of agricultural vegetables.

It is added, that chemistry points out tests and processes whereby waters, as well as marls and other gross manures, may be tried and analysed. But the virtue of water, when considered as a manure, does not reside in a single principle, like that of lime-stone. Water is capable of suspending, not only calcareous earth, but various other matters,—of animal, vegetable, and fossil origin: some of them friendly, others inimical, to vegetation. It would, therefore, it is thought, be imprudent in a practical man in this business to commit himself to theoretic guidance alone, while the theory of manures, and especially of watering land, remains so much involved

WATERING OF LAND.

involved in obscurity; and while trials in the field, on the very land which is desired to be improved, may be made with facility and prompt decision.

The effects of watering are remarkable in many instances: in Wiltshire, it is not uncommon to see, it is said, lands, where water has been diverted for the purpose of improvement, divided by a hedge or a ditch only, the grass on one side of which is of the most luxuriant nature and abundant growth, but on the other so diminutive that the strongest blades have never reached the height of three inches. The same is the case in other situations, which sufficiently marks the importance of the practice.

It will be necessary, before we state the different methods of performing the business of watering in different circumstances, to give some account of the implements which are requisite for the purpose, as well as some explanation of the terms employed in carrying on the work in the different modes. The first and principal instrument in the execution of the work is a proper level, of which the spirit one is perhaps the best. It is necessary for taking the level of the land at a distance, compared with the part of the river or other stream, from whence it is intended to take the water, to know whether it can or cannot be made to float the part designed to be watered. It is particularly useful in works of this sort on a large scale, though the labourers too frequently neglect the use of it, bringing the water after them to work by in-cutting the several parts that are to convey the water. It should, however, be mostly used as being more certain and correct. See *LEVEL*, and *WATER-LEVEL*.

A proper line and reel and cutting-iron are likewise absolutely necessary, as well as a breast-plough, which should be of the best kind, as being of great use in cutting turfs for the sides of the channels and other parts. See *WATER-Line and Reel*, *WATER Crescent*, and *BREAST-Plough*.

The spades used in this sort of work should have the stems or handles considerably more crooked than those in common use, the bit being of iron, about a foot in width, in the middle, terminating in a point, a thick ridge running down the middle part, from the top to near the point; the edges on both sides being drawn very thin, and kept quite sharp by frequent grinding and whetting: when they are become thin and narrow by wearing, they are used for the smaller trenches and drains. By means of the handles being made so crooked, the workman, standing in the working position in the bottom of the drain or trench, is enabled to make it perfectly smooth and even without any difficulty.

Both short and narrow scythes are also necessary, in order to mow and cut away any weeds or superfluous grass that may be present, during the running of the water in the trenches or other cuts; as well as forks, and long four or five-tined crooks or drags for pulling out the roots of the sedges, rushes, reeds, and other such matters, that may be in the large mains or other channels. These crooks should be made light, and have long shafts to reach wherever the water is so deep that the labourers cannot work in it, so as to remove such obstructions.

Wheel and hand-barrows, too, become necessary and useful, the former for removing the clods and earths to the flat or hollow places, for this use they may be made open, without sides or hinder parts; the latter are used where the ground is too soft to admit the former, and where the clods or other matters require to be removed during the time the land is in water. But when large quantities of earth are wanted to be removed, especially when to be conveyed to some distance, three-wheeled carts are proper.

And in all cases a stout large water-proof pair of boots is

absolutely requisite, having the tops made so as to draw up half the length of the thigh; they should be large enough to admit a quantity of hay or other such materials to be stuffed down all round the legs, and be kept well tallowed, in order to resist the running water for any length of time.

The terms used in the practice of watering are very numerous. A weir is a work thrown over or across a brook, river, rivulet, stream, main, or other such parts, the use of which is to divert the water; and when the hatches are all properly adjusted and in their places, to stop the whole current, in order that the water may rise high enough to overflow the banks, and spread over the adjoining land; or, by stopping the water in its natural course, turn it through mains or channels, cut to convey it another way, to some distant lands that are to be watered. See *WEIR*.

A sluice differs from the above simply in having but one thorough or opening, as when there are more than one it becomes a weir. It is applicable in small streams in the same way that the weir is in large ones. See *SLUICE*.

The covered sluice or trunk is constructed and had recourse to in all such cases, as where two streams of water are to cross each other at the point of discharge, and to serve as a bridge. The drain-sluice or trunk is that which is placed in the lowest part of a main, as near to the head as it can be formed, and put low enough to drain the main and other parts. It is put with the mouth at the bottom of the main, being let down into the bank; and from the other end of which a drain is cut to communicate with some trench-drain that is the nearest. It is used for carrying off the leakage through the hatches when shut down, to convey the water to other grounds, and for some other purposes. See *SLUICE*.

Hatches are flood-gates, and used for the same purposes: they are consequently differently formed in different cases; but such as have about a foot to take off, and let the water pass over so much of them, are thought useful by some in different cases of watering. Others suppose them the best when made whole and of good timber. See *HATCH*.

A carriage is a sort of small wooden or brick passage, built in an open manner, for the purpose of carrying or conveying one stream over another, and is useful in many cases, though very expensive in the practice of watering.

Head-main in watering land implies that part of the principal cut or channel which takes the water first out of a river or stream, and conveys it to such lands as are laid out for the purpose, by means of smaller mains and trenches. It is necessarily formed of various breadths and depths, according to the quantity of land to be watered; and to the length, or the fall of the ground it is cut through. Small mains are the next order of cuts for the distribution of water on lands, as connecting between the head-main and trenches. These smaller mains are mostly taken out of the head-main; and the only difference between them is, the one being much less than the other; they are commonly cut at, or nearly at, right angles with the other, though in some cases at many degrees less. The use of both these sorts of mains is to feed the various trenches and gutters that branch out in all parts of the land with water, and to convey it for floating the ground in an equal manner. By some these smaller mains are termed carriages, but improperly, as it is confounding them with the open trunk so named, as already seen.

The trench, in watering, is a shallow narrow cut or ditch made to take the water out of the mains for floating the land. It should always be drawn in a straight line from angle to angle, with as few turnings as possible. It is

WATERING OF LAND.

never made deep, but the width of it must be in proportion to the length it has to run, and the breadth of the pane of ground between that and the trench-drain. It should constantly be cut gradually narrower and narrower, in the wedge-form, to the lower end, in order to force over the water more equally.

The trench-drain is constantly cut parallel to the trench, and as deep as the tail-drain water will permit were necessary. It should always, where possible, be cut so as to come down to a firm stratum of sand, gravel, or clay. If the last, a spade's depth into it will be of great benefit. The use of it is to take away the water immediately after it has run over the panes of the land from the trench. It is not necessary to be brought up to the head of the land by five, six, or more yards, as the nature of the soil may be. The form of it is the reverse of the trench, being narrower at the head, or upper part, and gradually wider and wider, until it comes to the lower end, and empties itself into the tail-drain, which is a receptacle for all the water that comes out of the other drains, that are situated so as not to empty themselves into the river; and, consequently, it should run nearly at right angles with the trenches; but it is, in general, preferable to draw it in the lowest part of the ground, and to use it for conveying the water out of the ground where there is the greatest descent: this is commonly found in one of the fence-ditches; for which reason a fence-ditch is mostly made use of for the purpose, as answering the double use of a fence and drain at the same time.

The pane of ground is that part of the land which lies between the trench and the trench-drain, and is the part on which the grass grows, which is cut for hay: it is watered by the trenches, and laid dry by the trench-drains; consequently there is one on each side of every trench. The term pane is also applied to the part which is used, for taking off the produce.

The bend implies a stoppage made in different parts of such trenches as have a quick descent, in order to obstruct the water. It is effected by leaving a narrow slip of greenward ground across the trench where the bend is designed to be, and cutting occasionally a small part out of the middle of it in the wedge form. It is useful for checking the water, and forcing it over the trench on to the panes; which, if it were not for such bends, would run rapidly on in the trench, and not flow over the land as it passes along. The great art of watering land consists in giving to every part of each pane of ground an equal quantity of water, which is greatly promoted in this way.

The gutter is a small groove cut out from the tails of these trenches, where the panes of ground run longer at one side or corner than the other. The use of it is to carry the water to the extreme point of the panes. Those panes which are intersected by the trench and tail drains, meeting in an obtuse angle, want the assistance of these gutters to convey the water to the longest side. And another use of them is, when the land has not been so perfectly levelled but that some parts of the panes of ground lie higher than they should, a gutter is then drawn from the trench over that high ground, which would otherwise not be overflowed. Without this precaution, unless the flats were filled up, which should always be the case when materials are to be had, the water will not rise upon it; and after the watering-season is past, those places would appear of a rusty-brown, while a rich verdure would overspread the others; and at hay-time the grass in those places would scarcely be high enough for the scythe to touch it; while that around them, which has been properly watered,

will, from its luxuriance, be laid down. This neglect is, therefore, to be reprobated in most cases, as the great art of watering land is that of throwing the water regularly over all parts, those where it cannot rise of itself as well as others, and in carrying it off from those in which it would otherwise stagnate and be hurtful.

The catch-drain is an occasional ditch, sometimes cut for the purpose of carrying the same water into a second main or other part, for watering lower lands or panes of ground with the water that has been before used. It is made use of too in some other cases, as catching the water that is thrown forward.

Pond is used to signify any part where the water stands on the ground in watering, or in the tail-drain, trench-drains, or others, so as to injure the lands near them; and is occasioned by flats and irregularities in the surface of the grounds, as well as by other causes.

The turn of water means the space of land that can be watered at one time in any case; and is accomplished by shutting down the latches in all those weirs where the water is designed to be kept out, and opening those that are to let the water through them. The quantity or extent of land to be watered by one turn, must of course vary with the size of the river, brook, main, and other such parts, and by the plenty or scarcity of the water.

The bed of a river, main, trench, or other such part, is the bottom of any of them.

The head of any watered land is that part into which the river, main, or other such part, first enters. And the tail of it is that part where the water last passes off by the tail-drain into the course that is to take it away.

The upper side of a main or trench is that which, when they are made at nearly right angles with the river or other such part, fronts the place where the river, &c. entered. And, of course, the lower side is the reverse.

The upper pane of the land is that which lies upon the upper side of the main or trench when made at right angles with the river, &c. running north and south. Where, however, these run parallel with the river, &c. the panes on either side are not distinguished from each other.

Some other terms, which are used by the more modern writers on watering land, will be explained as we proceed in pointing out the nature of the business.

After noticing the manner in which water is artificially brought on and taken away from the land in watering, as already seen, the writer of the tract before alluded to remarks, that the art of watering land may properly be called floating, not foaking or drowning. Soaking the soil, similar to the effects produced from a shower of rain, is not sufficient for the general purposes of watering; nor will damming up the water, or keeping it stagnant upon the surface, like that in a pond, or on the fens, produce the desired effect. The latter, it is thought, may properly be termed drowning, because it drowns or covers all the grasses, thereby rendering the plants beneath it certainly aquatic, or the herbage disposed to take on such a change; whereas the herbage of a watered meadow or land should, from the form and circumstances of the ground, enjoy the full benefits of air and water. Practice has proved, it is said, that there is no better method of effecting this, than by keeping the water passing over the surface of the land with a brisk current, but not so brisk as to wash away the soil, and yet in sufficient quantity to cover and nourish the roots, but not too much to hide the shoots of the grasses: hence appears the nicety of adjusting the quantity of water; and hence it appears, too, that one main-drain, to bring the water on the upper side of the land, and another on the lower

WATERING OF LAND.

lower side to take it away, will not be adequate to all the purposes of such an accurate regulation. If the space between the upper channel, or *main-feeder*, and the lower one, or *main-drain*, should therefore be wider than what is proper for the due adjustment of the water, that is, so that every part of the space may have enough of water passing over it, and no part too much, then that space must be divided into smaller spaces by intermediate drains, which may catch and re-distribute the water. These, and the ground capable of being watered in this way, have this term applied to them, as they *catch* or collect the water and re-distribute it, being in well-formed lands never made more than eight or ten yards apart. As the water is brought by the main-feeder upon the higher side of a piece of ground, which slopes towards the main-drain, and down which sloping surface the water will very readily run, to persons unacquainted with watering, it does not at first sight appear necessary to make such a number of intermediate catch-drains; but it is proved by experience, that however regular the slope of ground may appear to the eye, the water will find a number of irregularities, force itself into gutters or channels, and defeat the purposes of watering, in the hollow places by excess, and in the high ones by the want of water. Hence the water that was scattered over the surface of the first space, being all collected in the catch-drain, may, by the skill of the floater, be let out upon those parts of the bed of ground below, which seem to need the greatest assistance.

As it is essentially necessary to possess full and complete command of the water in all cases of improvements of this nature, the works for the purpose should always be well-formed at first. Temporary means of making dams and hatches to divert the water out of its usual channel may, it is said, by the writer of the tract on watering land, suffice to try an experiment, or for a tenant who has but a short term in the grounds to be watered; but every land-owner, or other proprietor, who enters upon or undertakes such works in this temporary manner, sadly mistakes his own interest; indeed, it is frequently more difficult to repair than to renew upon large streams, where the foundations are not seldom destroyed or very greatly injured by the force of the water. The same principle holds good upon small streams, and even in the feeders and drains of watered land. Wherever the channels are so contracted as to make a fall, or much increase the rapidity of the stream, it is constantly disposed to wear away the sides of its channel, or undermine a dam. The repair of these defects will stand in need of land to be dug away and wasted each time, they are replaced with the loss of labour. The consequent ill-management of the water renders it more advisable, and perhaps cheaper, to make all such works of masonry. When works are well done at first the owner ever finds a pleasure and satisfaction in viewing them; and even the labourers feel much more interest in their good management, which is a circumstance not to be overlooked.

In the undertaking of business of this kind, it is necessary, before entering upon its execution, to fully consider whether the stream of water to be made use of will admit of a temporary weir or dam to be formed across it, so as to keep the water up to a proper level for covering the land without flooding or injuring other adjoining grounds; or if the water be in its natural state sufficiently high without a weir or dam, or to be made so by taking it from the stream higher up, more towards its source, and by the conductor keeping it up nearly to its level until it comes upon the meadow or other ground. And still further, whether the water can be drawn off from the meadow or ground in as

rapid a manner as it is brought on. Having, in addition to all these, too, an attention to all such other difficulties and obstructions as may present themselves, from the lands being in lease through which it may be necessary to cut or form the mains or grand carriers, from the water being necessary for turning mills, from the rivers or brooks not being wholly at the command of the floater, and from small necks of land intervening, so as to prevent the work from being performed to the greatest advantage, the operator may be in a situation to commence his works.

The water being thus under full command and regulation in every part of the land to be watered, by a proper direction, use, and form of the works, it is supposed necessary, in order to have an equal distribution, and prevent the waste of it, that no part of the meadow or land, either in the bed or catch-work mode, should be so formed as to be floated or watered directly from the main-feeder; but that all the main-feeders should be kept high enough to discharge the water into the small feeders with considerable velocity, and through a narrow opening. The motion of water is said to be truly mechanical; and that it requires a great deal of ingenuity, and a perfect knowledge of lines and levels, to make it pass over the ground in a proper manner. Each meadow or portion of land requires a different design, unless the land-owner or tenant makes up his mind to the heavy expence of paring off banks, and filling up such hollows as may be necessary to reduce it to some regular method, the construction to be varied according to the nature of the ground. This constitutes the difference between the watered meadows or lands of Berkshire and those of Devonshire. Those of the latter county being upon small streams carried round the sides of the hills, and are chiefly in catch-work; those of the former are near large rivers and boggy ground, being thrown up into ridges to create a brisk motion in the water; and also for the essential purpose of drawing off the superficial moisture which might be injurious to the grasses when shut up for feeding or mowing. Where there is much floating to be done with a little water, or rather where the great fall of a small stream will admit of its being carried over a great quantity of ground, and used several times, it is desirable to employ it in such a way, though meadows or land so watered are not to be considered as perfect models. If it should answer the purpose of a coat of manure upon such an extent of ground, it is all that can be expected, and will amply repay the expence. In all cases, losing fall is wasting water. All the drains of watered meadows or lands require no greater declivity than is necessary to carry the water from the surface; therefore, the water should be collected and used again at every three feet of the fall, if it be not catch-work. It is sometimes difficult to do this in bed-work lands; but where the upper part of the land is catch-work, or in level beds, and the lower part not too much elevated, it may be done. By collecting and using the water again in the same piece of ground before it falls into the brook or other course, a set of hatches is saved, and it is not necessary to be very particular about getting the upper part into high ridges, since that part of land which is near the hatches generally becomes the best, and the lower end of the field being often the wettest or most boggy in its natural state, requires to be thrown up the highest. If the land be of a dry absorbent nature before floating or watering, it is not necessary that it should be thrown up into high beds. There are many good meadow lands in the county of Wilts that have little work in them, and some that have neither feeder nor drain: but these are extraordinary situations that do not occur in almost any

other county, or they must, it is thought, have suggested the ideas already stated as to the origin of floating or watering. There is some reason, it is thought, from the natural warmth of peat-ground, which keeps it from freezing, that such land will produce an earlier crop of spring-feed than any other. At all events, it will first shew the advantages of watering, and gravel or sand may the next to it.

It has been suggested that if grass-land of the heavier kind could be ploughed in such a manner as to set the two furrow-slides or fods in a leaning position against each other with the grass sides outwards, the roots of the grasses would be perfectly dry all winter; the shoots would have the full benefit of the sun, and great advantage from mutual shelter. Upon wet land, this ploughing should be done the way the water runs. If the ground ploughed in this form before winter could be watered toward the spring, so as to give it a good soaking, it might be pressed down again to a level surface with a heavy roller. If these narrow ridges, too, were crossed with level trenches at every forty, fifty, or one hundred yards distance, according to the fall of the ground; and these trenches made to communicate with other main trenches, which should run up and down the slope, and supply or discharge the contents of those which are horizontal, such ground might be laid dry or wet at pleasure. And it is believed, that land so shaped might be floated or watered all winter with stagnant water to its great benefit, and probably in the spring too, if the water be changed at frequent and proper periods; for the water would remain only in the furrows, where there would be little or no vegetation, and the newly loosened soil of the ridges could not fail to absorb moisture, such as would promote the growth of the grass without any danger of putrefaction. The levels must be taken before a piece of ground be ploughed in this shape, and the earth taken out in cutting the cross-drains, be used in stopping the furrows on the lower side of them. Perhaps upon wet lands it would be necessary to re-plough them every autumn, or the strong lands might become too solid to receive the same benefit from the practice; and it will be necessary to level the ridges every spring, if the ground be mowed, but if summer-fed, it may as well remain in this form as any other. This easy method of getting land up into ridges, which are very narrow, gives to the surface all that inclination which is necessary for drawing off water, and is certainly so far likely to answer the purpose of watering. The water is thus under the same command as in any of the best-formed meadows or lands, and a much less quantity will be sufficient than under any other plan of watering. It is supposed that it might, probably, answer the purpose to float young wheat, or any other sort of grain, in some cases, by a similar method. It is thought that flat peaty ground, such as the level fens in Norfolk, which are subject to be covered a few inches deep every winter with stagnant water, would be much benefited by ploughing in this way before the floods commence. Some parts of it would thereby be raised above the water, and vegetate quicker in the spring, and the sedge matter growing up in the furrows, would in a few years raise them to the same level. The cross-drains, where on a declivity, would serve to catch and re-distribute the water, and the fall from one to the other must be very little. If this method be found not to do for watering, it is thought that four furrow-ridges of turf, with a small feeder upon each, would answer all the purposes of a more expensive system. There is always good grass by the side of the feeder, whether the water rushes over it or not, and a meadow or land of this nature would be nothing but feeders. It requires so little elevation of ridge and fall in

the feeders, that the water might soon be used again; therefore a very small quantity would suffice; and if there was a scarcity in the winter, the whole discharge might be stopped, and gradually lowered in the spring. This method would answer all the purposes of complete saturation, which seems to be one of the most essential parts of watering, and might be applied more or less, according to the time of the year. When the water is put on, it is supposed no grasses would sustain any injury by exclusion from the air for a day or two at the first application. If these ridges could be elevated but four or six inches above the furrows, it would give the surface nearly the same slope as the wider ridges of common meadows or lands; perhaps it would be better to begin ploughing the furrows wide at the ridge, and very narrow at the furrow, which would leave but narrow spaces for drains. If a piece of turf-ground were ploughed in such ridges by the common way of turning over the furrow, if it were set pretty much on edge, it is thought the grass between would soon cover the whole surface.

Ridges, too, might perhaps be made by beginning the two first furrows more apart than the usual width, thus leaving the width of one furrow between the two first to constitute the channel of the feeder. These ridges should be ploughed up and down, with only three or four inches fall between the cross feeders; and the water may be brought into use again at every other set of beds. If the ground require to be loosened every year, or every other, or two years or more, it will not be attended with much expense, and there will be no very great inconvenience in mowing ground in this shape, if the sides of the ridges be about a swath wide. It is thought that meadows or lands of this sort might be made for twenty-five or thirty shillings the acre, floated or watered with less water than catch-work, and have many advantages over it; namely, the water would lie more above the surface, would be more at command, and therefore changed more readily, and it may be pent up better to get a good soaking when scarce. This may be done more effectually in turns, and will run drier when the water may be taken off. It does not require much skill in the making or management. All the water will be let through nicks instead of running over a nice level edge, which in the first place is seldom made well, and in the next is difficult to keep in repair. This sort of work would, it is thought, have all the advantages of drains and feeders, whereas the same channels are obliged to serve for both in the common catch-work; it would require but very few or no stops, and consequently want but little attendance. It might be practised where there are six or eight inches of fall between the cross-feeder and cross-catch, as the water of each ridge, which should be short, may be led out by a fod with less trouble in the regulation than catch-work. See WEIR.

The whole of the channels and drains for carrying the water on or off the land, in the constant course and regular quantity which practice proves to be necessary, have two very distinct uses. The first sort or feeders bring a continued supply of water to make the slopes wet; and the latter by carrying it away, prevent the land from getting too wet in the time of floating or watering, and serve to render it dry when that operation is over, and to remove any superfluous moisture which may leak from the soil or fall from the clouds. The large ones which convey the water to the land, and along the main ridge to supply the others, are sometimes said to be the *main feeders*; and the branches that run along each ridge and distribute the water down the sides, the *floating feeders*. The first operation of floating or watering begins, or ought to begin, at the edges of these feeders; the main feeders being nothing more but channels or courses
along

WATERING OF LAND.

along which the water must pass, from the places where it can be found to the places where it is to have its effect. The place of its use lies between the floating feeder and the foot of the slope or drains, which are made in every furrow, for the purpose of catching the water; and which are said to be catch drains, and the large ones, which collect the water from these, main drains.

It is supposed that all floating or watering, in large rivers, may be done without constructing hatches, which are often attended with heavy expences and many inconveniences. If the proprietor has the land far enough up the river, nothing more is necessary, than to go thither and cut a channel out of it, which shall be deeper than the bottom of the stream. The water, which will be taken out in this new channel, may be dammed up by the hatches in it, at any place most convenient for getting it out upon the surface. To turn it into its old course down the river, nothing more is necessary than a hatch at the upper end of the feeder. Feeders constructed in this way will be extremely serviceable in time of floods, for by drawing both the hatches an entire new channel will be opened, which is generally much freighter than the old one. To contrive the shortest possible way to get the water upon the ground, it is evident that an obtuse angle is the best calculated for that purpose; it shortens the length of the feeders, facilitates the motion of the water, increases the velocity, and consequently preserves that natural warmth or motion which keeps it from freezing in the winter or stagnating in the summer. It also prevents the accumulation of scum, or whatever floats upon the surface, and enables the floater to distribute the water much more equally on every part of the work than if it went in a more circuitous course. The wind has less power to retard the motion of the surface, and the sediment which should go out upon the beds is less liable to lodge in the bottom of the feeders, and consequently the feeders will be cleared out with much less trouble and expence, especially if there be proper plugs or small hatches to draw up for the purpose of sending a stream through them. It may appear to some that these hatches are too expensive, or unnecessary, but practice proves that it is best to have them well done at first, which is doing them for a length of time. Inclined planes, too, are absolutely necessary for the purpose of watering. To form these between straight and parallel lines, it is requisite to dig away land where it is too high, and move it to these places where it is too low, to make such an uniformity of surface. The new-made ground will, of course, settle in hollows proportioned to the depth of the loose matter which has been lately put together, but such settlement will not take place until the new ground has been completely soaked with wet and dried again; consequently, these defects cannot be removed before the second or third year of watering; it will therefore require more skill to manage watered land for a few of the first years, than may be the case at any time afterwards.

In conclusion it is noticed, that however simple the construction of a watered meadow or land may appear upon a superficial view, those who enter particularly into the concern will find it much more difficult than is commonly supposed. It is no easy task to give an irregular surface that regular yet various form which may be fit for the overflowing of the water. It is quite necessary for the designer to have just notions of lines, levels, and angles; the knowledge of superficial forms will not be sufficient. Accurate ideas of solid geometry, somehow acquired, are absolutely necessary to put such a surface into the proper form for the reception of water, without the trouble and expence of doing much of the work twice over.

Division of Watering.—The practice of watering land may be divided or distinguished into two principal heads or modes; as those of performing it in flat work or flat-flooding, and in sloping or catch work. Each of these divisions has, however, many varieties in the methods of executing the business, as will be seen below.

In the former, or that of watering lands in flat-flooding, there must be a full supply of water, which serves only one turn, and is then carried off the field. There should be a very moderate but uniform declivity in the surface of the land, and the requisite expence be incurred by the undertaker. But though in such works a very small gradual declination will mostly be sufficient, there will be considerable variety in this particular, according to the actual form of the land. The most desirable and perfect declivity for this purpose has been found to be in the ridges, from the upper to the lower extremities of the field, one inch in every nine yards. With this gentle fall, the water passes over by the mere contraction of the feeder, without any stop; but such exact declivities are seldom had. It is also found that the declivity of the sides of the ridges, from the crown to the furrow, should be about two inches for every yard; so that, supposing the ridge to be ten yards broad throughout, and every side to be in the form of an inclined plain, declining in this proportion, the crown may be ten inches raised above the furrow, measuring by the surface at each part. In these proportions, however, there is great actual variety. It is by no means uncommon to find the ridges fourteen yards wide; and when the water is very scanty, they are sometimes twenty yards in width. Where there is a full stream of water, the narrow ridges are found to produce the greatest crops in proportion; but the expence of forming them is likewise greater. Where the field or land has an uniform surface, and the declivity suits, one principal feeder may serve the whole. It is to be cut so as to be the widest at the upper end, contracting all the way as it descends. Notches are to be cut in the bank on the side next the land; and a notch opposite to and communicating with each of the lesser feeders, in order to supply them all in succession with water. These smaller feeders, too, are to be formed so as to be the largest at the heads, contracting gradually as they descend, until near the lower end of the ridge, when the small feeder entirely disappears. The corresponding small drains are made somewhat less than the feeders, though not much less, and the proportions of the drains are reversed, being formed the largest at the lower ends, and diminishing into scarcely any thing at the upper ends.

But though the surface of the field or land should be uniform, yet if the descent in the line of the principal feeder be too rapid to admit of its giving supply to the lesser feeders, in a regular manner, without great stops or hatches, the method below may in that case be had recourse to. The main ditch may act as a conductor only, not as a feeder; and parallel to it the main feeder may be formed in several different parts, each of which is easily levelled up, so as to supply five or six ridges, and is itself supplied from the conductor, by simply adjusting a stop or hatch for every subdivided feeder. If the surface should consist of separate and gently rising swells, there must be a main feeder branching away from the conductor to supply every ascent, on the top of which this feeder is formed; while a corresponding drain is cut at the bottom, and the respective ridges are marked out and formed between the feeder and the drain.

If it should be necessary, some catch-work may be intermixed, so as to water the irregular portions of surface, which possess a degree of declivity answering to that mode

of watering; and too much of it to be conveniently and properly watered in flat flooding.

The ridges being formed, and all the feeders and drains cut out, and their materials placed and disposed in such a way as to render the surface as regular and correct as can at first be done; the seeds of proper grasses should in some cases be sown, but in others it will be unnecessary. When the land is ready in the spring, the seeds may be sown with a thin crop of some early grain kind, but it may be as well to sow the seeds alone towards the beginning of the autumn if the land be then ready.

In the latter mode of watering, or that of catch-work, the principle consists in floating as much of the surface, as can be done, in the way most suited to the form of the grounds; taking care to prevent the water from sinking or stagnating; and collecting it again to be a second time, or more frequently thrown over new surfaces of the land. In order to put it in the power of the floater to receive the water, and to throw it again over some other portions of the ground, there must be a declivity sufficient for such purposes. A smaller quantity of water may be enough for watering, according to this method, than is necessary in flat flooding; and as the water is accommodated to the form of the ground, and no ridges required, the expence of watering in this way is generally very moderate, in comparison with that of watering flat meadows or lands. It is well adapted, too, to those gentle declivities which produce very little in the state of nature, but may become highly valuable at little expence, when properly watered. On these and some other accounts, it would seem that all the preference to flat meadows or lands, that has been commonly claimed for them, is not due. At least, it admits of no question, that watering in catch-work, when properly executed, is a very beneficial and advantageous method.

The principal objection to this mode of watering is, perhaps, in the seeming unequal distribution of whatever nutriment the water may contain, which has certainly some weight in it; as the first surface over which the water passes, must of necessity have the advantage. It should not, however, be entirely forgot, that in most cases of land in such declivities the considerate farmer bestows most manure where the soil or land is the most thin and poor; and the water of catch-work meadows or lands does the same; the higher situated grounds receiving it and its benefits the first, and afterwards those which are lower, and, for the most part, richer, and deeper in point of earthy staple.

In this mode of watering, the feeders and drains are cut in a direction passing across the slope of the surface of the land; and having no greater fall, as the water flows in them, than to cause it to move gently and freely, without either stagnating, or acquiring such a rapidity, as might endanger the works. In order to accomplish the work in this easy way, the water may be introduced at an upper corner, where it passes gently, and by a very small declivity in the feeder across the slope, and overflows the surface below its tract. A drain, at a proper distance below, receives the water, and transmits it into another feeder, cut on the same plan as the former, where it again overflows, and is again taken up in a drain to be sent over new surfaces.

In this manner, a moderate quantity of water may float a set of different spots lying in a diagonal direction, until it arrive at length at the bottom of the watered grounds, and reach a drain which carries it off completely. An entirely new set of different spots may then be watered in the same manner, the drains in the first process, or case, acting as feeders in the second, and the contrary in other cases. But catch-work watering, so far as regards the method of per-

forming it, admits of almost an endless variety. A conductor with stops may be formed, pointing directly down a declivity, if the rapidity of the current be not suspected as dangerous for forcing up the channel in which it flows. From this conductor, feeders may be formed at right angles, to the right and to the left, or in either direction; and the stops in the conductor send the water into these feeders; which, being formed only a very little off the level, soon fill and overflow the grounds below them. The surplus water is collected in drains parallel to these feeders, which restore it to the conductor, whence it can again be diffused to right and left, in order to float a lower situated surface, from feeders constructed in the manner already seen.

There are many other ways of watering in different cases of this nature; but where the lands are necessary to be laid down into permanent meadows, the works should evidently be substantially executed at once, and with proper care and design, whether the method be catch-work or flat meadows or grounds.

Regular plans of this mode of watering may be seen in the last editions of Wright's tract on the "Art of floating Land," and of Young's "Farmer's Calendar."

The writer of the work on "Landed Property" has given practical directions for four different methods of applying it artificially on the surfaces of grass lands, which may be useful in guiding the practice of the inexperienced.

1st. Flooding or covering low flat Lands with stagnant or slowly-moving Water.—This is a mode which, it is thought, was formerly, perhaps, the only one in use, in this country, for enriching the bases of valleys by the means of water. In the midland districts, tradition, it is said, speaks of it with familiarity. And the remains of works that have been used in practising it, are still evident. Even in the western districts of the southern range of chalk hills, which have long profited more by watering, than all the other districts of the island, this, it is more than probable, has been heretofore the only method in use. It is indeed an interesting fact, it is said, that the far-famed long-grass mead of Orcheston, in the county of Wilts, is still watered in this manner. But it is conceived that there are now, however, few situations in which this method can be practised with the best effect. The one for which it is the most applicable is, it is supposed, a *drained morass*, or other flat moory ground, through which a stream naturally passes, or to which a sufficient supply of enriched waters can be led. A body of water, resting on a light spongy surface, tends to compress and consolidate it; while the sediment of foul waters, let fall in passing from an agitated to a stagnant state, further promotes this tendency. The rich moory meadows and pasture grounds, which are seen in various parts of the kingdom, were doubtless, it is thought, brought to their present profitable state, by being flooded with stagnant or slowly moving waters.

Another, and perhaps the only other, sort or class of lands, to which this method can now be properly applied, is *dry valley grounds*, which are composed of a sufficient depth of soil for the pasture of herbage, with a subsoil of flints, pebbles, or rough gravel, to draw off quickly the superabundant moisture that may be left in the soil, after its surface has been freed from water; and, thereby, to give vegetation the immediate freedom of action. But lands of this sort, having a sufficient command of water to flood them, are much less common, in this country, than those of the former class or kind. The valley of Orcheston is, however, in itself, it is thought, a sufficient stimulant for searching narrowly for lands of so valuable a formation, and which can command fertilizing water to flood them; as they may generally

WATERING OF LAND.

nerally be watered at less expence by this, than by any other method.

The method of flooding flat or dishing lands artificially with standing water, is simply, it is said, that of raising a dam across the lower end of the site of improvement, of a sufficient height to overflow the land, and proper strength to sustain the weight of the water; with a channel at each end, to carry away the overflow; and with a valve in the middle or lowest part to draw at pleasure.

Where the subsoil is not sufficiently absorbent and open to free the upper soil of superfluous moisture, presently after the body of water has been drawn off, a main drain should be run up into the area of the site, and lateral ones be branched off from that, to wherever the water is found to hang; whether on the surface or in the subsoil. But where the subsoil throughout is retentive, though but in a small degree, the land may be considered as improper for this mode of watering, as will be seen below.

2d. Watering flat Lands with running Water, when raised into Ridges.—This is a method of practice which is conceived to be modern when compared with that of flooding, drowning, or covering the entire surface with standing water, as being a spirited mode which is still, as a general practice, confined to one part of the kingdom. Among the chalk-hills of Wiltshire and Dorsetshire, but especially the former, there are large tracts of water-formed valley lands, which have long been watered with scientific accuracy and correctness. These lands, it is probable, were first brought to a firm state of sward, by flooding them, during a great length of time, with standing water; and have been since moulded into their present form; been raised into ridges, or other inequalities, in suitable manners, and properly watered.

It is proper and necessary, however, before so expensive a practice be recommended, to explain the principles on which it proceeds, and on which it may be profitably pursued and had recourse to; where suitable ground, and a sufficient supply of water, which is proper, can be employed. It is noticed that plants, as well as animals, have their natural elementary matters. That water plants, aquatics which root beneath the water, live but in this fluid, where they are secluded, in a certain degree, from air and heat. On the contrary, the agricultural vegetables of this country, among which are to be reckoned the more nutritious meadow plants, require a free communication of atmospheric air and heat, to every part of them: they cannot live with their roots immersed in water, nor flourish while water is lodged immediately beneath them. And between these two opposite tribes of plants, is found an intermediate one, which is somewhat amphibious, or partakes something of the nature of both,—the plants of which delight in water, yet can live, though not flourish, on dry land,—provided it be of a cool nature or quality.

It is stated that where the soil of low flat meadow lands of this nature, rests on a retentive base, the palustrian sort of plants seldom fail to intermix with the meadow herbage. In a season which is favourable to dry land plants, the superaquatics are kept in a dwarfish underling state. On the contrary, in a wet season they flourish; while the better herbage becomes weak and unproductive. If, through neglect, the soil or land be suffered to remain saturated for some length of time with water, the meadow plants dwindle, or die, and the ranker wet-land weeds take possession. Hence, in the practice of watering, the propriety of quickly relieving the soil or land from superfluous moisture or wetness, in order that the better herbage may gain the ascendancy; especially in the spring, when a few days of warm weather at the critical juncture may give the one or the other a su-

periority during the early summer months. Even in meadows where the superaquatics do not abound, the same principle of practice holds good; for it is well known to common observation, that flat retentive meadows, which do not readily shoot off surface-waters, are materially injured by a cold wet spring: by which the finer more nutritious herbage is cut off, or wholly checked; so that the hay-crop proves thin, is of small bulk, and of an inferior quality. But further, though it be evident that water, even standing water, may remain for a short time upon dry land-plants with impunity, especially in a cold season; yet wherever it is suffered to lie long on the surface, particularly during warm weather, there, dry land-plants, in general, are destroyed, are probably suffocated for want of that supply of air which *standing* water is incapable of affording them. Hence, it is supposed, appears to arise an advantage of watering with *running* water; and hence, too, the propriety of watering by *intervals*; in order to enable the plants to recover their strength, and to exert their natural powers of imbibing the nourishment the water may have provided for them, and thereby increasing their strength. Besides, the warmth which moving bodies, even agitated liquids, naturally generate, may be suggested as another advantage of watering with running water.

These considerations may, it is supposed, sufficiently explain the reason for laying up cool flat lands into ridges for the purpose of watering. Experience has well ascertained, it is said, that where calcareous water, at least, is spread over a sufficiently sloping surface of grass-land, the superaquatic plants disappear, while the more nutritious grasses luxuriate. On the contrary, where the same sort of water is suffered to loiter on a flat soil, lying upon a retentive base, the grosser wet-land plants prevail. And further, that the same or similar water in its nature, thrown over the same or a similar sort of soil, with the same turn of surface, but with a dry absorbent base, produces luxuriant crops of valuable herbage. And, from long continued observations on facts of this nature, has doubtlessly arisen, it is thought, the present *practice* of Wiltshire and its neighbourhood.

The work of raising flat lands into water-mead ridges in these cases, is directed to be performed in this manner. In a suitable situation, where the stream of water can be properly received to begin and mark out a plot of the green sward, or land, of the proper length and breadth for the purpose. Then if to be done by the spade, to roll back the turf after it has been cut, and form the earth of the soil into the proper shaped convex ridge, being careful in forming it, to keep the best of the mould constantly toward the surface, and leaving the opening on the ridge eight or nine inches or more deep, and nearly level; the end towards the stream being made somewhat higher and rather wider than the other, that the water may flow evenly over every part of the ridge. The turf is then to be returned, being careful to replace it evenly and firmly along the sides of the trench in the middle; and cut a drain on each side of the ridge thus formed, with proper outlets to carry away the waste water. Lastly, raise a channel between the ground and the source of the water, to conduct it into the watering-trench; and continue to adjust the ground until the well flow evenly over every part of it. The most proper forms, and the degrees of convexity which are the most suitable in different cases, will be seen below.

This work may be performed either with the spade or with the plough. The former is the more expensive method, but it is the more accurate, and sooner brings the improvement to profit. By the spade, the natural earth and soil are again distributed on the surface. By the plough much of them is

WATERING OF LAND.

buried under the ridges, while the furrows are left destitute. Where there is a great depth of fertile soil, the plough may be used with better effect than where the soil is shallow.

The next consideration is the elevation and convexity of these meadow ridges. On the principle offered, it is said, the steeper the sides are formed, the more beneficial will be the effect of the work. But it is not less certain that the expence of it will be proportionally great. Something may depend on the nature of the materials of which the ridges are to be formed, and the method of forming them. If, in moving the materials, a regular stratum of flints or gravel can be buried, at a proper depth, as an open subsoil, a small degree of elevation will be sufficient. In ordinary cases, one foot of rise to sixteen feet and a half, or a statute-pole of base, will suffice; provided the drains between the beds be sunk to a sufficient depth. One foot of rise to five feet and a half of slope, or eleven of base, may be considered as the maximum of elevation in these cases. On these premises, it is concluded, that a ridge set out one statute-perch in width at the base, requires an elevation of from nine to eighteen inches at the ridge; one of two perches in width, an elevation of from eighteen inches to three feet, according to the nature of the materials by which it is formed. In respect to the *turn* of surface, or form of the slope, there are sufficient reasons why it should be convex, not a regular inclined plane, nor of a concave or hollow cast. A regular sheet of water spread over a sloping surface has a natural tendency to break into streamlets, and to collect into partial currents. In the process of watering, this effect is produced in part, by the unevenness of the surface it is spread over, and the obstructions it meets with in its descent, as well as by the natural propensity of falling waters to collect into a body; and the steeper the descent, the greater freedom of action this propensity acquires. Hence, the propriety of giving the water a gentle descent on the upper part of the slope, in order to preserve the entirety of the sheet as far down the side of it as may be; and this is effected by the convex form, which also gives firmness to the sides of the trench. Besides, a convex surface, while it lessens the descent at the ridge, increases it at the foot of the slope, and thereby hastens the drying in that part; to which the superfluous moisture of the entire slope tends, and where noxious plants are most liable to gain a footing; the earth or soil being there kept the longest in a state of saturation.

The width of these convex beds is a matter of much consideration. In what has been said of their elevation, it plainly appears that the expence of forming them is in proportion to their width. An acre of ground may be raised into beds of a rod wide, with the mentioned slope, at half the expence that another acre can be formed into those of two rods in width, and the same slope: the latter requiring to be raised at the ridge twice the height of the former; besides the work in this case being within a smaller compass. And from what has been said of the form of the slope, it is equally clear, that water may be more evenly spread over a narrow than over a wide or deep slope; and that a narrow bed will dry more quickly than a wide one of the same soil and substrata. Nevertheless, there is an advantage of wide ridges, which, in some situations, may more than over-balance all their inconveniences. A given quantity of water will float twice the quantity of ground, though perhaps not with twice the profit, when raised into beds of two poles wide, that it will in those of one perch in width, besides the current expences of management being less. If, however, the quantity of water be great in proportion to the extent of ground, or if it can be collected again, and spread over other lands belonging to the same owner, which lie below those

that have been watered, narrow ridges may claim a superiority. Hence, the proper width of watered meadow ridges depends much on soil and situation, and on the quantity of water proportionate to the quantity of ground. In the neighbourhood of Salisbury, the prevailing width, it is said, is ten yards, nearly two perches. In the vicinity of Amesbury, there are some of three times that breadth or width, but they are nearly flat. From one to three poles may fairly, it is thought, be set down as the ordinary limits of width.

In respect to the arrangement of these meadow beds, and the general economy of watered meadows or lands of this nature, almost every thing may be said to depend on the particular circumstances of the given site. But supposing a copious stream of good water to pass through a flat of water formed land, in a dilatation of the base of a valley; and supposing the situation of it to be nearly level from side to side of the same, or to have a gentle descent, the banks of the stream towards the outer margins; a case which often occurs where flat lands have long been liable to the overflow of foul waters. In this case, the beds require, it is said, to be run across the valley in a direct or oblique manner, as the descent may point out; and the water to be conducted to them by an artificial channel, winding on each side of the natural stream, with a main-drain near each outer margin, leaving room for a carriage-way between it and the foot of the bank of the valley; and where the grounds to be watered are wide, other road-ways may be left between the conducting trenches and the bed of the brook or rivulet. These dry slips of land are useful, not only in conveying away the crop, but in furnishing comfortable lodging-grounds for pasturing stock when the area of the land is moist. It follows, of course, that these road-slips should be watered with caution, late in the spring and during the summer months. The most eligible method of raising the water high enough to fill the trenches, is that of placing folding-gates, like those in use for navigable canals, across the stream, at the upper end of the ground to be improved. In summer, or when the water is not wanted for use, the gates may be thrown open, and fastened back, to give free passage to floods. But during the time of watering they are kept shut, to throw a constant supply of water into the main trenches. If the descent downward of the valley be considerable, the main trenches or conducting channels require to have stops, or rather checks, placed across them, at distances proportioned to the descent, in order to fill with due effect the working trenches, the mouths of which open into the conducting channels; and, to gain more perfect command of the water, the mouth of each acting trench should be furnished with a regular valve, to admit just water enough to supply the given ridge while under watering, and to close the entrance effectually when it is laid. A lifting-board in the form of a shovel, with a short handle, and sliding in upright grooves made in the faces of two slender posts, joined together within the ground, becomes a simple and desirable regulator for the purpose. And where a meadow ridge happens to be long and much declining, a circumstance which should, as much as possible, be avoided: checks are likewise requisite to be placed in the working-trenches, to assist in distributing the water evenly over its surface. These checks are formed in different ways. Two thick tough sods placed in the trench, so as to leave an opening between them narrow enough to force a sufficient quantity of water over the sides of the trench above them, and wide enough to let the remainder pass down freely into the lower part of the trench, form a ready and not ineligible check for this purpose; as the opening may be easily widened or narrowed

rowed at pleasure. If the descent straight across the valley be not sufficient, where the descent down it is considerable, it is advised to direct the beds obliquely across it, and by this easy mean gain the required fall. But where the base of the valley is wide, so that the length of the beds, if run out from the natural stream to the outer bank, will be too great, as from fifty to a hundred yards, wind a conducting trench along the foot of the bank, as well as by the side of the brook or rivulet, and sink a deep drain in the midway between them. As to what regards the dimensions of working trenches, they should vary according to the breadths and lengths of the beds to be watered. The wider and deeper they are formed, the more freely a large body of water will pass along them. Hence it is evident, that the upper end of a long trench should have the larger dimensions, in order that a sufficient supply of water may pass freely to the further end, where the dimensions are required to be less; as the uniform contraction serves as a continual check to the water, and thus tends to force it in its passage over the sides of the trench. From six to fifteen inches wide, and from four to ten inches deep, may serve to give a general idea, it is said, of their dimensions.

3d. *Watering by Spreading running Water over naturally uneven Surfaces.*—In the more western counties of this country, but particularly in Devonshire, this practice has been established time immemorial. Even tradition there speaks not of its origin. The spring-waters that issue from the slate-rocks, which are there the prevalent substructure, are of a fertilizing nature; and the steep valleys that there abound are mostly covered with a rich deep soil, fit for hay-ground. Such circumstances may well serve, it is said, to account for the prevalence and antiquity of the practice in that part of the kingdom. Something of this practice, on a small scale, too, has been long in use in different parts of the country for spreading the overflowings of dung-yards and pits, and the wash of home-stalls over grass-lands lying below them. Of late years, also, it has been employed in different districts, in distributing the waters of more copious streams; and numerous instances still remain in which the practice may be extended with great and valuable effects.

If the quantity of water be small, whether it flow from a farm-stead, or a spring of superior quality, it should, it is said, be collected in a proper place, whenever it is not employed on the ground; more especially in the spring months, while the hay-crop is growing, in order to be able to liberate it, should its growth be arrested by a dry season, and to meliorate the soil as soon as the crop is off the ground for the benefit of the after-growth. The ground or situation of improvement is mostly given in the source of the water, or the point at which it can be commanded. Where this is a matter of choice, it is generally advisable to run the channel of supply along the brink or brow of a slope, as above: thus giving the flatter lands above it to the plough, to which in upland situations they are best suited, and the steeper to the scythe, as watered hay-grounds, for which they are the most eligible; extending the ground downward to the foot of the slope, and to the flatter lands beneath it, provided their subsoil be absorbent and open, and the given quantity of water be sufficient for the whole extent. The canal or artificial water-course from the natural stream or other source of the water, to the ground of improvement, requires a certain fall, to give a due degree of current to the water it may convey. If the motion of water in a supplying channel be sluggish, part of it is liable to sink, and be lost by the way. Slowly moving water does not tend to make the bottom of the channel firm and water-tight, like a

living stream: nor will a channel of the same size convey an equal quantity of water in the same time; nor will it clear itself so well from obstructions, as with a quicker current. On the contrary, dead water gives the suspended matter, which should be conveyed as nourishment to the plants, an opportunity of being deposited by the way in the form of mud, for want of agitation, and thereby fouling the channel. On the other hand, if the current be made too rapid, it is liable to wear the channel, and to cause unnecessary repairs. Besides, where all the height that can be properly got is required, every foot of superfluous fall contracts, unnecessarily, the field of improvement. On the grounds of practical experience, it is supposed, that one *per cent.* as one inch, foot, or yard of fall, in every hundred inches, feet, or yards of distance, is, in ordinary cases, the proper fall: this giving an active but inoffensive current. Under the above circumstances, and where the length of channel required is great, one-half *per cent.* may be made to suffice. Two-thirds of the ordinary fall gives a degree of life to the stream, and may, in many cases, be eligible and proper.

In setting out water-courses of this nature and sort, the use of the level is necessary; and the best forms of such courses, whatever the size may be, are those of inverted arches, as clearing themselves better when low in water, and giving firmer banks on the lower sides than is the case with square flat-bottomed steep-sided trenches. The modes of performing the work, and of laying them out properly, must be directed by the particular turn of the surface of the grounds.

In the low lands which lie at the feet of the sloping grounds, the natural surfaces of which are sufficiently uneven to admit of running water being spread over them, without the assistance of art; and the substrata of which are sufficiently absorbent and open, to permit them to dry quickly, after the water is taken off: the method of watering, where they lie pretty regularly shelving, is to lead the water along the higher side of the land, and to draw it off by a main-drain on the lower side; straight working trenches and corresponding drains being cut, downward of the area, so as to spread the water over the whole, without suffering it to lodge on any part of the surface. This is that which may be distinguished by the Devonshire practice, or manner of watering.

Where, however, the surface is more irregular, lying in natural swells and ridges, with dips and hollows between them, the water is to be led along the tops of such higher parts, without regard to the straightness or regularity of the trenches; and the drains to wind up the hollows and lowest ground with the same irregularity. There are two ways of ascertaining the true lines of the trenches and drains in cases of this nature. The one is by flooding the entire area, where it can be done, and driving down levelling-pegs over every part of it, so as to leave their heads uniformly level with the surface of the water; which being let off, the shortest pegs shew the proper lines for the trenches, the longest those of the drains. This method was used by Bakewell, in Leicestershire. The other, which has occurred in the writer's experience, is attended, it is said, with less trouble and inconvenience. The higher parts are readily ascertained, and the lines of the trenches accurately traced by a proper levelling implement; artificial mounds being raised between the detached knolls when wanted. After the fresh-made ground has properly settled, and the trenches have been duly formed, the water is turned on; and by this ready mean, the proper lines of the drains are accurately given. This is an easy way of watering valley lands; and

where the irregularities of surface are sufficiently great, and the subsoil absorbent, it is very eligible; especially, if in making the trenches and drains, the turf and soil so raised be applied in adjusting the natural defects of the surface.

In the watering of more steeply sloping grounds, as the sides of hills, and the lower banks of valleys, in what may be termed the Devonshire practice, as having been long there and thereabouts chiefly established; as there, the sides of the valleys lie in or nearly in their natural states; many of them appear as if they had never been subjected to the plough; and those which have been in tillage, have been laid down again to grafs with nearly their natural surfaces. The practice of laying up soils into high arable ridges, has never, perhaps, gained a footing in that part of the kingdom. In these cases, the conducting channel being led along the brink, and across the upper part of the slope, as advised, the working trenches are to be supplied from it by means of checks and valves, as already seen. The distances between the working trenches are to be regulated by the steepness and evenness of the surface. Wherever the sheet of water is seen to break, and to divide into numerous streamlets, there a trench is required to catch and respread it; the working trenches, in this manner of watering, acting in the two-fold capacity of trenches and drains: fresh supplies of water being let down from above, to the lower trenches, as occasion may require.

Where the depth or downward length of the slope is great, or where an additional supply of water offers itself, and where reservoirs are formed at different heights, an additional main-channel is required, to lead a fresh supply across the midway of the slope. This main-trench likewise receives the waste water from above; and, like the working-trenches, acts at once as a supplying-channel, and as a receptacle of the waste water: hence, a given quantity of water will float a much larger extent of ground in this manner of watering, than in watering ridges, raised on level ground; though, it may be presumed, not with equal benefit.

In forming the trenches of whichever sort, the turf and loose earth that are raised out of them, and which are not wanted to make their lower sides firm and level, are to be used in filling up the channels and dimples that naturally happen in the face of the slope; in order that the water may spread more evenly over it, and thereby to lessen the requisite number of trenches. To the same end, if hillocks or small protuberances occur, as they generally do on natural surfaces, they are to be lowered by turning back the turf, using their contents as above, and returning the sods to smoothed surfaces. But, where the knoll is large, water may be led by a narrow branching trench to its top, and be thus spread evenly over its sides. The proper descent or decline of the working trenches depends, in some measure, on the press of water that enters them. One quarter *per cent.* may serve as a guide in setting them out: first making them of inferior dimensions, and then turning on the water: afterwards enlarging them, and in doing this, adjusting them in such a manner, that the water will flow evenly out of them, from end to end. The shorter the acting trenches are made, the more easily they may be regulated without the incumbrance of checks, which should be avoided as much as possible.

4th. Watering sloping Grounds that have been raised into Ridges by Cultivation, and are in the State of Grafs.—In watering ridges on slopes, or such shelving grounds as have formerly been in a state of aration, in which they have been raised into high wide convex beds, resembling those advised above, for flat meadowy surfaces, and have been laid

down to grafs in that form; a practice which, it is supposed, has been common to many parts of the kingdom, especially where the common-field system prevailed; the direction of the ridges being mostly directly downward of the slope. In this case, it would be in vain to attempt to spread water over the surface, in the manner usually practised on more even slopes. And if it be thrown into open trenches, cut along the tops of the ridges, agreeably to the practice in use for level grounds, and according to the ordinary practice of watering the lands now under consideration, the operation becomes very imperfect. For, if the descent be considerable, the water will unavoidably flow out of the trenches in streams immediately above the checks; and the sides of the ridges will consequently be watered partially. These difficulties in spreading water evenly over ridges on steeply shelving surfaces, have led some industrious managers to throw down the ridges, and return the slopes to their natural states. But this, where the ridges are high and wide, is very troublesome and expensive if done by hand; and if performed by the plough, is greatly injurious and hurtful to the land for many years. A better method has therefore been had recourse to by the writer. Instead of leading the water down the ridges, it is thrown into the furrows, and spread over the sides of the beds by means of crooked trenches, winding, in the festoon manner, horizontally, or nearly so, across them, and led more effectually over their tops by pointed trenclets depending from the festooned parts. These winding trenches, like those across plain sloping surfaces, act both as feeding-trenches and as drains, or collecting trenches, to respread the water evenly over the ground, immediately below them: thus keeping the entire ridge covered with an even sheet of briskly moving water. When the upper ends of the ridges are sufficiently watered, the water is to be let down the furrows to the parts below; or if the ridges are short, their whole length may be watered at once, by letting the water partially down the furrows to the lower parts, by the means of cuts of proper widths, made with a sharp tool across the lower sides of the trenches, where they cross the furrows: these simple regulators acting as checks in the common modes of watering. The distances between the trenches, as well as their form, must always vary with the steepness of the slope or descent, and the shape of the ridge.

Considerable tracts of land in North Wales have been watered in somewhat this manner of late years.

In concluding, it may be stated on the best authority, that the beneficial practice of watering, by some of the methods which have been suggested above, may be greatly extended and applied in different parts of the country where it has yet been but little tried, as on the fenny lands of the counties of Lincoln, Norfolk, Cambridge, Northampton, and, perhaps, some others, where it is particularly desirable, as well as the bottoms of the chalk-hills in different districts, as Yorkshire and Suffex, and the vales of Hertfordshire, the chalky parts of Buckinghamshire, Oxfordshire, and Suffolk, which are peculiarly fitted for the purpose; besides many others where good waters are afforded for making such improvements on grafs-lands.

WATERING Live-Stock, in Agriculture, the business of giving and providing them with water. The work is effected in different ways, and by different means. See *DRINKING-PONDS, MADE STREAMS, WATER-CISTERNS, WATER, Rain, Collecting of, SPRING, Artificial, WELL, Field, &c.*

WATERING Plants and Fruit-Trees, in Hot-houses, Stoves, &c. in Gardening, the practice of throwing water over them in different intentions. The common modes of applying water have been spoken of in considering the general practice

of garden-watering, and under the heads of the different plants, as they may require it; but the nature of its application, in these cases, may be explained in the present place.

For plants in these situations, Mr. Fordyce has advised the use of simple water only, in clearing them from different nuisances to which they are exposed, though lime-water in other cases may be more powerful and have a better effect, as will be seen below. It is directed to be applied in this manner. About four o'clock in the afternoon a barrow-engine is to be filled with soft water, or such as has been exposed to the sun through the day, and wheeled along the foot-paths of the houses, where they are wide enough to receive it, and the whole of the plants sprinkled with the fluid, by pressing the finger on the top of the pipe of the engine, in order to spread the water somewhat in the manner of a fine shower of rain, playing the engine and throwing the fluid likewise against the top-lights and shelves of the houses, until the water stands an inch deep in the paths of the houses. A small copper engine may be made use of, and answers very well, when a barrow-engine cannot be got into the houses. It may be had in most places. But if an engine should not be conveniently at hand, which can be got into the houses, the front-lights may be opened, or, where there are no front-lights, the top-lights may be slid down, and the water be thrown in at the fronts or tops. When this operation is begun, if in the inside, every light must be close shut down; and if the water be thrown in at the fronts or tops, one light only is to be kept open, which is immediately to be shut, when that part of the house, which is opposite to it, is sufficiently watered; then proceeding to open others until the whole be properly watered. The houses after this are to be kept close until the next morning; which will cause such an exhalation from the glass of the houses, and the beds that may be in them, if there should be any, that the plants will, it is said, be covered all over with steam or vapour; which will infallibly destroy and clear them of the vermin and other hurtful matters that may be upon them, especially those of the plant-louse and coccus kinds. This sort of watering is, however, to be repeated every afternoon, in the time of hot weather only. By it a great deal of labour in watering will be saved; but such plants as stand in need of much watering, should have the water given them before the sprinkling of the houses is begun. In most cases, the plants will have imbibed all the moisture before morning, and the paths of the houses will be perfectly dry.

As it sometimes happens that in hard winters, when strong fires are under the necessity of being kept in the stoves or other houses night and day, that the plants which stand on shelves in those of the dry kind, are so parched up, that the leaves drop off, as from deciduous trees in the autumnal season, which renders them very disagreeable in their appearance; it should be prevented or remedied by watering, in the manner directed below by the same writer. About eight o'clock in the morning, when the sun shines out, and there is the appearance of a fine day, water is to be thrown into the houses until the floors are covered to the depth of nearly two inches; they being kept shut the whole day, unless the heat rises very high, which is seldom the case at such a season of the year, but when it does happen, the doors may be opened to admit a little air. By the middle of the day, the water becomes entirely exhaled, and the floors quite dry. The operation may be repeated two or three times in a week in sunny weather. The plants in the course of a week's time begin to recover, or throw out new foliage, and in a fortnight or three weeks become in full leaf again, displaying themselves in a fine manner;

This sort of watering is greatly useful on many other occasions, as in the growth of plants in the pits of such houses.

Fruit-trees in such houses may also be watered in the same manner with much benefit in some cases; but for those against walls, a lime-water prepared by putting thirty-two gallons of soft water to half a peck of unslaked lime is recommended to be used in this manner. With the clear liquid, after the lime has subsided, the engine is to be filled, and a good watering given to the trees, throwing a considerable part of it forcibly under the leaves, and spreading it finely by the means directed above; at the same time, wheeling it backwards and forwards, that no parts of the trees may be missed. This should be performed when the weather is cloudy, or when the sun is off the wall that contains the trees. Where the trees are on an east wall, the watering may be begun about half past eleven o'clock; if on a north wall, the watering may be done the first thing in the morning; and when they are on a south wall, it may be executed about four o'clock in the afternoon: it is to be repeated once a day for six or seven days in succession. If, however, there should be cold northerly or easterly winds, or frosty nights, such watering should be discontinued until the weather becomes more mild and temperate. Care is constantly necessary that the trees get dry before night, and that no watering takes place while the sun is upon them. Care is likewise to be taken not to water them with any of the grounds of the limey liquid, which would injure the leaves, and make the trees look very unsightly.

This sort of watering, with the use of lime and wood-ash dust to the under-sides of the leaves, are found extremely effectual in destroying and clearing away every thing noxious about the trees, and in rendering them healthy and productive. See WATERING, in *Gardening*.

WATERING-Pots, Pans, or Cans, are such contrivances of this nature as are suited for pouring water over seeds, plants, trees, &c. in pots or otherways in a fine showery divided state, they being provided with strainers or roses of a finer or coarser kind for the purpose, well adapted to their spouts. They are particularly convenient for potted plants of all sorts, as well as many other kinds. They form the principal mode of hand-watering.

WATERING Sheep, in *Agriculture*, the supplying them with water. This is particularly necessary in the management of flocks in some situations, as on the South Downs; and as there is there no other water than what is to be collected by some artificial method, ponds are constructed for retaining such water as falls in rain; those, for this use, are commonly made circular, and very gently sloping to the centre; the bed very strongly rammed down to prevent any loss by soaking through the chalk. As ponds are liable to become leaky, and to be spoiled by a hard frost, they are made by lining them with chalk, puddled and trod down until it makes a sort of plaister floor. If a little good stone lime were sifted evenly over the whole and trod well in with the chalk, it would probably effect the business of rendering them perfectly retentive of the water under all circumstances.

In Italy the sheep-flocks were regularly watered morning and evening, as is evident from Columella, and the practice has probably considerable utility, especially in dry situations.

WATERING-Syringe, in *Gardening*, a large kind of garden syringe employed for throwing water to some height over trees or plants, in rather a forcible manner, in the way of a stream, for clearing away insects and other matters, as well as some other purposes.

WATERING *the Soil of Tillage Land, in Agriculture*, the practice of improving ploughed ground, and the crops upon it, by the application of water.

The outlines of a plan for watering arable or tillage crops and lands, that has long been familiar to the writer on the Management of Land, are first to form the soil into flat beds or ridges, with intervals, or trenches, directed somewhat obliquely across the slope, or general descent of the field or ground; namely, so as to dip from one quarter to one half *per cent.* beneath the dead level; this declination being equally calculated to communicate and carry off water. The width of the beds is to be regulated by the nature of the land. Absorbent soils may be laid into wider beds than those which are repellent, or of the stiff heavy kind, that are less prone to draw away the water.

The depth of the trenches should vary according to the quality of the water, and the intention of using it. For merely moistening the land, in a dry season, with ordinary water, the trenches, it is conceived, should be deep, so as to lodge the water in the subsoil, rather than the soil above it. But when an enriched water is to be used to fertilize the soil, and encourage the growth of the crop during its early stages, it requires to be communicated immediately to the pasture of the plants; consequently, in this case, the beds should be narrow, and the trenches no deeper than just to prevent the water from overflowing.

When the water is necessarily required to be conducted to the uppermost corner of the field or open ground, to be continued and conducted down the slope, across the higher ends of the beds, and to be forced into the trenches, by the means of regulated checks, placed below their mouths, as occasion may require; it should be either suffered to run with moderate streams along the trenches; or, if the quantity be small in proportion to the extent of ground, it may be checked at proper distances, so that the whole of it shall be absorbed, thus going over the ground, and repeating the watering as the quantity of water, or the sufficiency of moisture may direct.

WATERING, in the *Manufactures*. To water a stuff is to give it a lustre, by wetting it lightly, and then passing it through the press, or the calender, whether hot or cold. See **TABBING**.

WATERLAND, DANIEL, D.D. in *Biography*, was born in 1683, at Wasely, in Lincolnshire, where his father was rector, and sent to Magdalen college, Cambridge, in 1699, for the completion of his education; of this college he was elected a fellow in 1704, took his degree of M.A. in 1706, and became a private tutor. His tract, entitled "Advice to a young Student, with a Method of Study for four Years," published at this time, was popular, and passed through several editions. In 1713 he was nominated master of his college, and presented to the rectory of Ellingham in Norfolk. On occasion of taking his degree of B.D. in 1714, he distinguished himself by defending before the regius professor of divinity the negative of his thesis, "Whether Arian subscription be lawful?" Being chosen chaplain in ordinary to king George I., he was nominated, on his majesty's visit to Cambridge, D.D., and incorporated in the same degree at Oxford. Distinguished as a champion of orthodoxy by his "Vindication of Christ's Divinity, being a Defence of some Queries relating to Dr. Clarke's Scheme of the Holy Trinity," printed in 1719, he was appointed in the following year the first preacher of lady Moyer's lecture in favour of the divinity of Christ. He also published an answer to Dr. Whitby on the same subject, and in 1721 he was presented by the dean and chapter of St. Paul's with the rectory of St. Austin and St. Faith. His "History of the

Athanasian Creed," vindicating it against the objections of Dr. Clarke, was published in 1723, and his preferments to the canonry of Windsor, the vicarage of Twickenham, and the archdeaconry of Middlesex, kept pace with his publications of this nature. His remarks on Dr. Clarke's "Exposition of the Church Catechism," printed in 1730, engaged him in a controversy with Dr. Sykes on the sacrament of the Lord's supper. Against Tindal's "Christianity as old as the Creation," he published his "Scripture Vindicated," and his "Christianity Vindicated against Infidelity." On these treatises, Dr. Middleton published remarks, and they were defended by Dr. Zachary Pearce. In 1734 Dr. Waterland made an attempt for refuting Dr. Clarke's opinions in a "Discourse of the Argument *à priori* for proving the Existence of a First Cause;" and in this year, having declined the office of prolocutor of the lower house of convocation to which he was chosen, he published his treatise "On the Importance of the Doctrine of the Trinity," which he regarded as fundamental, avowing his high respect for the authority of the fathers in this and other articles of faith. In 1736 he commenced a series of archdiaconal charges on the subject of the eucharist, arguing against the opinion of Hoadley on the one hand, that it was a mere communicative feast, and against that of Johnson and Brett, on the other, that it was a proper propitiatory sacrifice. But a complaint under which he laboured, and which required repeated surgical operations, endured by him with exemplary patience, at length terminated his life in December 1740, in the 58th year of his age. A collection of his sermons was published after his death. "As a controversialist," says one of his biographers, "though firm and unyielding, he is accounted fair and candid, free from bitterness, and actuated by no persecuting spirit." Gen. Biog.

WATERLAND, in *Geography*, an island in the South Pacific ocean, discovered by Le Maire and Schouten, in the year 1616. It is represented as a low uninhabited island, sandy, and full of rocks, with plenty of trees on the border, but neither cocoa-nuts nor palmettoes. Some cresses and Indian salad were found, and some fresh water in ditches. No soundings for anchorage were discovered. S. lat. 14° 46'. W. long. 149° 30'.

WATERLANDIANS, in *Ecclesiastical History*, a sect of those that were called the gross or moderate Anabaptists, consisting at first of the inhabitants of a district in North Holland, called *Waterland*; whence their name. They were also called *Johannites* from John de Reis, who, assisted by Lubert Gerard, composed their confession of faith in 1580. This confession far surpasses, in respect both of simplicity and wisdom, all the other confessions of the Mennonites; though it has been alleged, that it is not the general confession of the Waterlandians, but that merely of the congregation, of which its author was the pastor.

This community, says Mosheim, has abandoned the severe discipline and singular opinions of Menno, whom, nevertheless, they generally respect as their primitive parent and founder. They are, however, divided into two distinct sects, which bear the respective denominations of *FREISLANDERS* and *Waterlandians*; and are both without bishops, employing no other ecclesiastical ministers than presbyters and deacons. Each congregation of this sect is independent on all foreign jurisdiction, having its own ecclesiastical council or consistory, which is composed of presbyters and deacons. The supreme spiritual power is, nevertheless, in the hands of the people, without whose consent nothing of importance can be carried into execution. Their presbyters are, generally speaking, men of learning, and apply themselves with success to the study of physic and philosophy; and there is a public professor,

feſſor, ſupported by the ſect at Amſterdam, for the inſtruction of their youth in the various branches of philoſophy, and ſacred erudition. One of theſe Waterlandian ſects was divided, in 1664, into two factions, of which the one were called GALENISTS, and the other APOSTOOLIANS, from their reſpective leaders. Moſheim's Eccl. Hiſt. vol. iv. vol. v.

WATERLOO, ANTHONY, in *Biography*, a Flemiſh landſcape painter of great abilities, is generally ſuppoſed to have been born at Utrecht, about the year 1618; it is certain that he reſided there the greater part of his life, and the ſcenery of his pictures is found in the environs of that city.

His landſcapes are characterized by the greateſt ſimplicity of compoſition; the entrance into a foreſt, a broken road with a bank and a few trunks of trees, a ſolitary cottage, a mill, &c. are made intereſting by the exquisite touch, and beautiful colour and chiaro oſcuro, with which he treated them. His ſkies are clear, and his clouds float in air; his colouring, however, is ſometimes too ſtrongly contraſted with yellow foregrounds and blue diſtances, and offend the eye for want of being more broken. He marked the characters of his trees admirably, in form and colour. His pictures are by no means common, as they are not numerous. He occupied himſelf very much in etching his own deſigns and views, and his productions in that art are as valuable as his pictures, in point of truth and ſkill; and will always continue to be a ſource of pleaſure and improvement to the artiſt and the connoiſſeur. His plates, according to Bartſch, amount in number to 150, not entirely completed with the point, but finiſhed with the graver, to ſoften and to invigorate them. It is to be lamented that he ſunk an early prey to habits of intemperance.

WATERLOO, in *Geography*, a village of the Netherlands, between 12 and 13 miles from Bruffels, ſituated behind the ſkirts of the fine beech foreſt of Soignies, rendered famous by one of the moſt ſevere and ſanguinary battles which modern hiſtory of war records, fought in its vicinity on Sunday the 18th of June, 1815, between the duke of Wellington, who commanded the Britiſh, Hanoverian, German, and Belgic army, and Napoleon Buonaparte, who conducted the operations of the French forces. The ground on which the battle was fought is ſaid not to exceed two miles from north to ſouth, including the whole from the rear of the Britiſh to the rear of the French poſition; and from eaſt to weſt, from the extremity of the left to that of the right wing of the contending armies, is about a mile and a half in extent; ſo that the ſanguinary reſult of the battle has been attributed in ſome degree to the limited ſpace in which they were engaged, and the conſequent intermixture of the two armies. The poſition of the French troops is repreſented as the beſt, becauſe the eminence occupied by them was higher, and the aſcent ſteeper than ours, and better adapted to attack and defence. The village of Waterloo, which is not ſeen from the field of battle, was occupied on the Saturday night previous to the battle by the duke of Wellington, the principal officers of his ſtaff, the prince of Orange, lord Uxbridge, ſir Thomas Picton, ſir William de Lancey, and other general officers. The French army in the Netherlands, is ſaid to have amounted to 130,000; and after the loſſes of the 15th and 16th, and the detachment of two corps under marſhal Grouchy, there muſt have remained at leaſt 90,000 men, with which Napoleon took the field on the 18th of June; while, after allowing for the loſſes of the allies on the 16th, which were very ſerious, it muſt appear that there was a great diſparity in regard to numbers; as it may be deduced from a ſtatement,

founded upon the lateſt return to the Horſe Guards, previous to the battles of the 16th and 18th, that the extreme force Britiſh and German was 46,221 men, under the duke of Wellington, to which we may add 22,000 for Brunſwickers and Dutch, ſo that the whole could not exceed 68,221 men; or, as it is elſewhere ſtated, there could not be in action a greater number than 64,000 men to ſupport the attack of the whole French army. From the adjutant-general's office, 6th November 1816, it appears that the effective ſtrength of the Britiſh army, preſent at the battle of Waterloo on the 18th of June 1815, was 74,040, including the army of obſervation. It is moreover obſerved, that the hoſtile army conſiſted of the beſt troops of France; that it was a regular and diſciplined army, even before the Bourbons quitted France, and that from the return of Buonaparte every thing had been done to render it effective; it was indeed the force which had been ſelected and combined to act upon the northern frontier. Whereas the allied army, the Britiſh part excepted, was almoſt wholly a green army; the allies, particularly the Dutch, Belgians, Hanoverians, and troops of Naſſau, being chiefly young ſoldiers.

Previously to the grand and deciſive battle of Waterloo, the campaign had commenced on the 15th of June by an attack upon the outpoſts of the Pruſſian army, commanded by field-marſhal prince Blucher. The points of concentration of the ſeveral corps of his army were, Fleurus, Namur, Ancy, and Hannut. Buonaparte advanced the ſecond corps of his army by Thuin, along the banks of the Sambre, upon the town of Charleroi, and drove the advanced poſts of general Ziethen's corps back upon the bridge of Marchienne. After a very ſmart action, the Pruſſian general was obliged to retire behind the river, and collect his corps near Fleurus; and as he conſidered Charleroi untenable, the troops ſtationed in that town were withdrawn, and the French cavalry entered it about mid-day. The Pruſſians defended their advanced poſts with bravery; and it was only the overwhelming force that was brought againſt Ziethen's corps, which induced that general to withdraw his advance, in order that he might concentrate his whole force near Fleurus.

On the evening of this day an officer arrived at Bruffels from marſhal Blucher, to announce that hoſtilities had commenced. The duke of Wellington received his diſpatches, whiſt he was ſitting after dinner with a party of officers. The troops were ordered to hold themſelves in readineſs, to march at a minute's notice. Before midnight a ſecond officer arrived from Blucher, and the diſpatches were delivered to the duke of Wellington in the ball-room of the duchefs of Richmond; and he gave his orders to one of his ſtaff-officers, who inſtantly left the room. In the midſt of the reſt that ſeemed to reign over Bruffels, the drums ſuddenly beat to arms, and the loud call of the trumpet was heard from every part of the city. The whole town became inſtantly an univerſal ſhow of buſtle. The ſoldiers aſſembled with their knapſacks, and every kind of warlike preparation threw the town into a ſtate of agitation. But before eight in the morning, the ſtreets, which had been filled with buſy crowds, were empty and ſilent; the great ſquare of the Place Royale, which had been filled with armed men, and with all the appurtenances of war, was now quite deſerted. The duke of Wellington had ſet off in great ſpirits, obſerving, that as Blucher had moſt probably ſettled the buſineſs, he ſhould perhaps return to dinner.

When the direction by which Buonaparte intended to penetrate into Belgium had been aſcertained, the duke of Wellington immediately gave orders for the army under his command

command to concentrate on the extreme of its position, near the great road from Brussels to Charleroi, and in a line between Nivelles and Namur. The fifth division of the British army, with the corps of the duke of Brunswick-Oels, left Brussels about 2 A. M. on the 16th, and advanced towards the position where the whole army was ordered to assemble.

One brigade of the Dutch troops, which was in advance towards Charleroi, had been attacked, when the Prussians fell back on the 15th, and driven from its advanced position near Frasnes; but the prince of Orange having moved up another brigade of the same army, they were able to repulse the enemy, and in the evening they regained the greater part of the ground which had been lost throughout the day. On the morning of the 16th, prince Blucher, who was determined to meet Buonaparte with all his strength, had posted the army under his command on the heights between the villages of Brie and Sombref, and to some distance beyond Sombref. In front of this line, he occupied the villages of St. Amand and Ligny with a very considerable force.

Buonaparte, as soon as he had passed the Sambre, directed the great body of his force against the Prussian line. Marshal Ney, who commanded the left wing, was directed to advance by Gosselies and Frasnes, and attack the British position; his force consisting of the first and second corps of infantry, and four divisions of cavalry.

The third, fourth, and sixth corps, with the guard in reserve, were ordered to attack the Prussian position in front, while the fifth corps under Grouchy, and a division of cavalry, were detached towards Sombref, on the Namur road, with the view of manœuvring on that flank.

On debouching from Fleurus, Buonaparte had an opportunity of reconnoitring the position of marshal Blucher with more precision. He immediately placed the first corps belonging to the left wing under Ney, with two divisions of heavy cavalry, behind the village of Frasnes, on the right, and at a little distance from the Brussels road, where it was to form a reserve, that could be brought up to support either his attack upon the Prussians, or Ney's attack upon the British. The third corps was ordered to advance in column to carry the village of St. Amand, while the fourth corps, supported by the guard and the cavalry, was ordered to attack Ligny.

The enemy advanced in overpowering masses upon St. Amand, where the action first commenced on the morning of the 16th. The brave Prussians defended this part of their advanced position with great firmness, and it was not till after a long and sanguinary conflict, that they were obliged to yield for a time to superior numbers. The fourth corps commenced its attack upon the village of Ligny about mid-day, and by one o'clock P. M. the action may be said to have become general throughout the whole of the extended line of the allied British and Prussian armies. Grouchy by that time had attacked the extreme left beyond Sombref, and Ney had come in contact with the advance of the army under the duke of Wellington, near Frasnes. But it was in the villages of St. Amand and Ligny, that the greatest struggle for victory took place, between the contending armies. There the battle continued for five hours, it may be said, almost in the villages themselves, as the movements forwards and backwards, during that period, were confined to a very narrow space. Fresh troops were constantly moved up on both sides; and as each army had immense masses of infantry behind that part of the village which it occupied, these served to maintain the combat, as they were continually receiving reinforcements from the

rear. Upwards of 200 pieces of cannon were directed against the villages, and they were frequently on fire in many places.

About 4 o'clock, prince Blucher placed himself at the head of a battalion of infantry, and charged with them into the village of St. Amand. After a dreadful struggle, he gained possession of the greater part of it. The enemy were panic-struck, and the victory seemed so doubtful, that Buonaparte was obliged to send in all haste for the first corps, which he had left in reserve near Frasnes; at the very moment too, that it had become equally necessary to marshal Ney, whose columns, having been repulsed by the fifth division of British infantry, were retiring in great confusion.

The advantage which Blucher had so nobly gained, was of little importance to the general action in which his troops were engaged. At Ligny, the battle still raged with unabated vigour; and though the evening was far advanced, the victory remained undecided. The badness of the roads, and the difficulties which general Bulow had to encounter in his march, prevented his corps from getting up on the 16th; so that Blucher had only three corps of his army in position; and though they had repulsed every attack which had been made upon them, the danger was becoming urgent, as all the divisions were engaged, or had already been so, and there was no reserve at hand.

As the night advanced, the enemy, favoured by the darkness, made a circuit round the village of Ligny, with a division of infantry on one side; and, without being observed, got into the rear of the main body of the Prussian army, at the same moment that some regiments of cuirassiers forced their passage on the other side of the village. This movement decided the day, and field-marshal Blucher was obliged to commence his retreat; yet his brave columns, though surprised, were not dismayed. They formed themselves into solid masses, and, repulsing every attack which the enemy made upon them, retired in perfect good order to their original ground, upon the heights above the village, and from thence continued, unmolested, their retrograde movement upon Wavre.

This movement of the marshal's rendered necessary a corresponding one on the part of the duke of Wellington; and he retired from the farm of Quatre Bras upon Genappe, and thence upon Waterloo, the next morning of the 17th at 10 o'clock.

The duke of Wellington, having given orders for the army under his command to concentrate on the left, proceeded with the fifth division and the duke of Brunswick-Oels' corps, in the direction of Charleroi. About two o'clock on the afternoon of the 16th, the head of the British column reached the farm of Quatre Bras, so named from its standing near where the roads from Brussels to Charleroi, and from Nivelles to Namur, cross each other. The advance of the enemy under Ney, who had again driven the Dutch troops from their position near Frasnes, had nearly reached the same spot; and general Kempt's brigade had scarcely time to deploy from the great road, before it was attacked by the enemy's cavalry, supported by heavy masses of his infantry. Nothing could exceed the daring intrepidity of the French troops at this moment; their success on the 15th, and confidence in their leader, added to the natural bravery of the troops, made them advance with almost a certainty of victory. The sudden appearance of overwhelming masses of cavalry, and the rapidity with which they charged our infantry, before they had time to throw themselves into squares, created some little confusion in one or two regiments. Indeed, so daring were the

WATERLOO.

French cuirassiers, that a regiment actually cut into the square of the forty-second Highlanders; but they paid dear for their temerity, as few ever returned to their lines; and the Highlanders had ample revenge for the loss of their brave colonel sir Robert Macara. The third battalion of the Royal Scots, twenty-eighth, and first battalion of the ninety-fifth, were warmly engaged for several hours on the left of the Brussels road; while general Pack's brigade, consisting of the forty-fourth, seventy-ninth, and ninety-second regiments, with the forty-second already mentioned, succeeded completely in repelling the enemy on the right, after an equally arduous contest.

About 4 o'clock, the first division under major-general Cooke, and third under lieutenant-general sir Charles Alten, came up, and were also immediately engaged. The enemy was now driven from his ground, and obliged to retire to the position which he had occupied the night before, and where he had some difficulty in maintaining himself, until the darkness put an end to the combat. The troops of the duke of Brunswick distinguished themselves very much on the afternoon of the 16th; and his serene highness was unfortunately killed at the head of his brave hussars.

At day-light on the morning of the 17th, the duke shewed his whole force, and challenged the enemy to fight; but they did not seem disposed to accept the challenge; and therefore both he and prince Blucher took up their respective positions; their movements having been communicated to each other, and Blucher having been requested to support the duke in case of an attack on the next day with two divisions of his army. On the 17th no movement of any consequence took place.

The position which the British army now took up, had been chosen with great judgment, from its proximity to the extensive forest of Soignies. The village of Waterloo lies upon the great road from Brussels to Charleroi, embosomed in the forest; and a few scattered houses extend to another small village called Mont-Saint-John: about a quarter of a mile in front of this latter village, there is a rising ground which crosses the great road already mentioned, and extends from a farm-house called Ter-la-Haye on the left, to the village of Merbe-le-Braine on the right, crossing also the road from Brussels to Nivelles, which diverges from the road to Charleroi at the village of Mont-Saint-John. It was on this rising ground that the allied army, commanded by field-marshal the duke of Wellington, or more properly the first corps of that army, took up its position on the evening of the 17th of June. The second corps, under the command of lord Hill, (with the exception of the fourth division and the troops of the Netherlands, under prince Frederick of Orange, who were left to guard an important position at Halle,) was placed in reserve on the right of the position, and in front of the village of Merbe-le-Braine, with its right resting on Braine-la-Leud. The infantry bivouacked a little under the ridge of the rising ground, and the cavalry in the hollow ground in rear of the infantry. Excepting a few round shot which the enemy occasionally fired while our troops were deploying into their position, nothing of any moment occurred during that afternoon or the whole of the night.

It had rained almost incessantly during the greater part of the 17th, and the weather was very tempestuous during the night. The ground afforded no cover for the troops; so that generals, officers, and men, were equally exposed to the rain, which fell in torrents. Buonaparte slept at the farm-house of Caillou near Planchenois; and his army halted in the neighbourhood of Genappe. The duke of

Wellington slept at a small public house in the village of Waterloo.

As soon as day-light appeared on the morning of the 18th, the British army could perceive, from its position, immense masses of the enemy moving in every direction, and before two o'clock the whole of his force appeared to be collected on the heights and in the ravines, which ran parallel with the British position.

The French army, when concentrated in front of the position of the allies, consisted of four corps of infantry including the guard, and three corps of cavalry, the whole number of men being uncertain, and probably overrated by those who state them at 120,000.

At 11 o'clock every thing seemed to indicate that the awful contest would soon commence;—a contest in which victory was obliquely and valiantly disputed on both sides, but which at last terminated in the complete triumph of the duke of Wellington, and total defeat and political annihilation of Buonaparte. The weather had cleared up, and the sun shone a little as the battle began, and the armies within 800 yards of each other, the duke of Wellington, with his usual quickness, had soon perceived the nature of the attacks that would be made upon his line; and when the troops stood to their arms in the morning, he gave orders that they should be formed into squares of half battalions, and in that state await the enemy's attack.

Marshal Ney, as soon as Buonaparte's order was communicated to him, directed the division of infantry commanded by Jerome Buonaparte, to advance upon Hougoumont; and about half past eleven o'clock, the first columns of this division made their appearance upon the ravine, or rather hollow ground, which leads down from the public-house of La Belle Alliance to the Chateau. The two brigades of artillery belonging to general Cooke's division had taken up a position on the ridge of the hill in front of the line of infantry, and the moment the enemy made his appearance, our nine-pounders opened upon his columns. The artillery officers had got the range so accurately, that almost every shot and shell fell in the very centre of his masses; so great was the effect produced by these few guns, that all Jerome's bravery could not make his fellows advance, and in a moment they were again hid by the rising ground from under cover of which they had but just emerged. This, which was the commencement of the action, was considered a very favourable omen by our brave fellows who witnessed it; and for a short time they were much amused with the manœuvres of Jerome's division, and the cautious manner in which it seemed to emerge from its hiding-place.

This state of things, however, did not continue long, as other great movements were observed to be preparing throughout the enemy's line. A powerful artillery was brought to bear upon our guns that had so annoyed his first advance, and general Jerome's troops gained the outskirts of the wood, where they became engaged with our light troops. By mid-day the cannonade was general.

The great object of Buonaparte, in this important battle, was evidently to force our centre, and at the same time turn our right flank; so that by surrounding and taking prisoners, as it were, one half of our line, he might completely paralyse and destroy the effect of the other half. Unfortunately, our centre was the weakest part of our position, and upon that part he directed his first grand attack to be made about noon.

An immense mass of infantry, followed by a column of upwards of twelve thousand cavalry, advanced upon the points occupied by the third and fifth divisions, and the left

of the Guards, covered by a fire from upwards of one hundred pieces of artillery. These columns, which seemed to advance with a certainty of success, were led by count d'Erlon in person. They advanced almost to the muzzles of our muskets; but here they soon found they had Britons to contend with; our fellows gave them a volley; and, cheering, rushed on to the charge, which they did not stand to receive, and our cavalry emerging from the hollow ground where they had hitherto been concealed from the enemy's view, passed through the openings between the squares, and charging the enemy's cavalry, succeeded completely in dispersing them, and driving them back upon their own line.

In this conflict, which was dreadful while it lasted, the enemy was baffled in all his attempts, and, besides the killed and wounded, lost several thousand prisoners and an eagle; but the British army had also to lament the loss of its brightest ornaments, and his majesty, one of his best officers. The gallant sir Thomas Picton fell, mortally wounded, in leading on the fifth division.

About 3 o'clock, when Buonaparte found that Jerome's division could not drive the guards from Hougomont, he ordered the chateau to be set on fire. The shells from several mortars which were brought to bear upon the houses, soon had the desired effect: but our troops, retiring into the garden, did not yield one inch of their ground; and the only thing which the enemy gained by this cruel measure, was the destruction of a few of our wounded, who were too ill to be removed, and who fell a prey to the flames. The troops in La Haye Sainte, having expended their ammunition, were obliged to retire for a moment from that point, and the enemy got possession of the house and garden; but as soon as a reinforcement of our troops could be moved up, he was driven from that as well as from every other point which he had attacked: and at no period during the day, notwithstanding the heavy masses of infantry and cavalry which were advanced against our centre, time after time, was he ever able to force our position; and the possession of the advanced post of La Haye Sainte for a few minutes, may be said to have been the greatest advantage he ever gained. The battle continued to rage with unabated fury, and the number of brave men who were continually falling on both sides was very great, while the rapidity with which the columns of attack succeeded each other, seemed to indicate for a time, that the resources of the enemy were inexhaustible. The artillery on both sides was well served: but Buonaparte had upwards of two hundred and fifty pieces in the field; while the train of the allied army under the duke of Wellington did not exceed one hundred guns, nine-pounders and six-pounders. Notwithstanding our inferiority in this arm, which was still more apparent from the size of the enemy's guns (being twelve-pounders) than from their numbers, ours were so well fought, that it is allowed by all, they did equal execution.

About 2 o'clock, the duke of Wellington dispatched an officer of his staff to the head-quarters of field-marshal Blucher, to ascertain his movements, and to know when it was probable his advance would come in contact with the enemy. This officer found the Prussian general at the village of Lasnes, where he gained the information required.

At half past 7 o'clock, the issue of the battle was still doubtful. The greater part of lord Hill's corps of the British army had been moved up at different periods to the support of the first corps. The whole of Bulow's corps, and part of the second corps of the Prussian army, had arrived at their position near Frichermont, and their attack in that direction was sufficiently powerful to oblige the

enemy to give way on his right; which Buonaparte having observed, conceived that the moment was now arrived when he must put an end to the engagement. He informed his generals that the firing on the right was occasioned by the arrival of Grouchy's corps. This gave fresh hopes to his troops already beginning to despair, and immediately he gave orders to form the last column of attack. This column was composed principally of the guard, which had hitherto suffered but little; he gave directions for the whole of the line to second this effort, upon which he said the victory depended, and placing himself at their head, they advanced in double quick time.

These veteran warriors, so long esteemed the first troops in Europe, advanced across the plain which divided the two armies, with a firmness which nothing could exceed; and though our grape and canister shot made dreadful havoc in their ranks, they were never disconcerted for a single moment. Our infantry remained firm in their position, until the enemy's front line was nearly in contact with them, when, with the usual salute of a well-directed volley, and a British cheer, they rushed on to the charge with bayonets. This charge even the Imperial guard could not stand against, and those undaunted troops, who at one time considered themselves the conquerors of the world, were obliged to give way. In this attack the British and French guards were, for the first time, perhaps, fairly opposed to each other. The shock for a moment was dreadful. The enemy refused to take or give quarter, and the carnage was horrible. At last the whole of their ranks was broken, all discipline was at an end, and they began to give way in the utmost confusion. The duke of Wellington, who was on the spot, was not inattentive to the manner in which the enemy retired from this attack, and, though his left was still pressed, he ordered the whole line of infantry, supported by the cavalry and artillery, to advance. This order was no sooner given, than our brave fellows rushed forward from every point. In a moment they carried the enemy's position, and obliged him to retire in great disorder, leaving in our possession a number of prisoners, and upwards of one hundred and fifty pieces of cannon, with their ammunition, besides two eagles. Before the disorganized masses of the French had cleared the ravine by which they retired, the right and left of the British line were nearly in contact, and the enemy in a manner surrounded. What added greatly to the confusion of the beaten foe, was a gallant charge by general Ziethen's corps upon his right flank, at the moment the British advanced in front. Blucher, who had joined with his first corps at the time this decisive charge was going on, advanced with his gallant troops; and about nine o'clock the two field-marsals met at the small public-house called La Belle Alliance, and mutually saluted each other as victors.

The British army, which had been so warmly engaged for upwards of nine hours, was now halted, and the pursuit left to the brave Prussians. Though they had already marched many leagues, all fatigue was forgotten when in the presence of their enemy. About half-past nine field-marshal Blucher assembled the whole of his superior officers, and gave orders for them to send every man and horse in pursuit.

It is not easy to ascertain the number of those who were killed and wounded, from the 15th to the 18th days of June inclusively. The loss of the guards, in killed and wounded, in the defence of Hougomont, amounted to 28 officers, and about 800 rank and file. The foreign corps (Nassau and Brunwickers) lost about 100. Within half an hour, it is said, 1500 men were killed in the small orchard

WATERLOO.

of about four acres at Hougomont. The loss of the French was enormous. The division of general Foy alone lost about 3000, and their total loss in the attack of this position is estimated at 10,000 in killed and wounded. Above 6000 men of both armies perished in the farm of Hougomont; 600 French fell in the attack on the chateau and the farm; 200 English were killed in the wood; 25 in the garden; 1100 in the orchard and meadow; 400 near the farmer's garden; 2000 of both parties behind the great orchard. The bodies of 300 English are buried opposite the gate of the chateau; those of 600 French have been burnt at the same place. The wounded at Quatre Bras, 16th of June, are stated upon the report of the adjutant-general, to be 5000; but no estimate is given of the killed, who must have been very numerous. On occasion of Blucher's retiring to Wavre, he is said to have had 14,000 men killed and wounded. The loss of the British, as stated in a letter dated June 19th, since the 16th, must have exceeded 5000. In the battle of Ligny and Quatre Bras, Napoleon is said to have lost 10,000 men. The total of the killed and wounded of the British soldiers, as returned from the War-office July 1815, amounts to 9755 persons. The total of the killed, wounded, and missing of the royal artillery in the battles of the 16th and 18th of June 1815, comprehends 32 officers, 15 serjeants, 285 rank and file, and 529 horses. The loss of the Dutch in killed, wounded, and missing, is stated to be 4136. The Prussians are said to have lost 33,120.

According to the French accounts their loss, at the battle of Fleurus on the 15th, was 10 killed and 80 wounded, and that of their enemy 2000, of whom 1000 were prisoners. The loss of the Prussians on the 16th could not be less, as they say, than 15,000 men, and their own 3000 killed and wounded. At Quatre Bras they say, that the English lost from 4 to 5000 men; and that theirs, which was very considerable, amounted to 4200 killed and wounded. They make no statement of that of the 18th.

The total loss of the British, Hanoverians, and German legions from official reports, from June 16th to the 26th, 1815, is 11,084; and the computed losses of the Dutch and Prussians during the campaigns in the Netherlands were, that of the Dutch as above stated 4136, and that of the total Prussian loss 33,132.

It appears from the list of killed and wounded from the official returns, June 16 to June 26, 1815, that an immense number of officers, several of whom were high in rank, is included in one or other of these classes. In the former, are the names of the duke of Brunswick-Oels, colonel Cameron, lieutenant-colonel Canning, lieutenant-colonel sir F. d'Oyly, colonel sir H. W. Ellis, lieutenant-colonel sir A. Gordon, colonel sir W. de Lancey, and colonel sir R. Macara, lieutenant-general sir T. Picton, major-general sir W. Ponsonby, &c. &c.; and in the latter we find the prince of Orange, the earl of Uxbridge, colonel Hon. A. Abercromby, lieutenant-general sir C. Alten, major-general sir E. Barnes, major Beckwith, lieutenant sir H. Berkeley, lieutenant-colonel sir H. Bradford, major Cameron, lieutenant-colonel Cameron, lieutenant-colonel R. H. Cooke, colonel sir J. Ellay, captain Hon. E. S. Erskine, lieutenant-colonel sir R. C. Hill, lieutenant-colonel Macdonald, colonel Hon. F. Ponsonby, lieutenant-colonel Fitzroy Somerset, earl of Uxbridge, &c. &c.

After the most diligent research, amidst confused and contradictory accounts, it is difficult, if not impossible, to ascertain the exact number of the killed and wounded, on both sides, in this sanguinary and decisive conflict.

Honourable and prosperous as was the issue of this battle,

we cannot forbear regretting that so many valuable lives should be sacrificed on occasions of this kind, and we also lament the condition of those who are wounded and maimed, and rendered helpless for the residue of their years. We applaud the spirit that has actuated such multitudes, and disposed them to confer honour on the name and memories, or to impart to the succour and supply, of those who have fallen or suffered in the service of their country.

The singular importance of this victory, the pre-eminent talents of the commander-in-chief, and the heroism displayed by the officers, commissioned and non-commissioned, and by all the privates, on this interesting occasion, entitled them to the gratitude of the government and of the country, and to such tokens of respect as were thought to be most appropriate to the occasion. Accordingly, it was resolved on the 23d of June, that the thanks of both houses of parliament should be given to his grace the duke of Wellington, prince Blucher, and the allied armies, officers and soldiers. The prince regent also granted the dignity of a marquis to earl Uxbridge and his heirs. The house of commons agreed June 29th 1815, in an address to the prince regent, requesting him to direct a national monument to be erected in honour of the splendid victory of Waterloo, and to commemorate the fame of the officers and men of the British army, who fell gloriously upon the 16th and 18th of the said month; and more particularly of lieutenant-general sir Thomas Picton, and major-general the Hon. sir William Ponsonby; and that funeral monuments be also erected in memory of each of these two officers in the cathedral church of St. Paul, London. The prince regent has also been pleased, in the name and on behalf of his majesty, to grant promotion to 52 majors, recommended for brevet-rank, for their conduct in the battle of Waterloo, to be lieutenant-colonels in the army; and to 36 captains to be majors, with commissions respectively, dated from June 18, 1815. His royal highness has also appointed major-general sir James Kempt, to be knight grand cross of the most honourable military order of the Bath; and major-generals G. Cooke, Maitland, and F. Adam, to be knights commanders of the said order, and a number of other officers to be companions of the most honourable military order of the Bath, upon the recommendation of the duke of Wellington. The king of the Netherlands has given the duke of Wellington the title of prince of Waterloo, and the states-general have settled upon his family an estate annually producing 20,000 Dutch florins, (2000*l.*) consisting of woods, &c. in the neighbourhood of La Belle Alliance, Hougomont, &c. The king of Saxony has also conferred upon the duke his family order of "The Crown of Rue;" and the grand duke of Baden has conferred upon him his order of "Fidelity" of the first class, accompanied with a gold snuff-box, enriched with diamonds of great value. The emperor of Austria has conferred upon a number of officers the cross of a commander, and of a knight respectively of the order of "Maria Theresia." The emperor of Russia has also conferred decorations of different classes of the orders of St. George, Anne, and Wladimir, on a number of officers. The king of the Low Countries has also conferred decorations of different classes of the "Wilhelm's" order upon certain officers. The king of Bavaria has conferred decorations of the different classes of the order of "Maximilian Joseph," on certain officers; all these in testimony of their respective approbation of their services and conduct. The prince regent has granted the dignity of a baron of the United kingdom of Great Britain and Ireland unto the right honourable lieutenant-general Rowland baron Hill and to his heirs; and in token of his high approbation of the distinguished bravery and

WATERLOO.

and good conduct of the first and second life-guards at the battle of Waterloo, he has declared himself colonel in chief of both these regiments. He also declares that he shall approve all the British regiments of cavalry and infantry which were engaged in the battle of Waterloo, being permitted to wear on their colours and appointments, in addition to all other badges and devices, the word "Waterloo," in commemoration of their distinguished services on the 18th of June 1815; and he also approves of all the ensigns of the three regiments of foot-guards having the rank of lieutenants, and that such rank shall be attached to all the future appointments to ensigncies in the foot-guards, in the same manner as the lieutenants of those regiments obtain the rank of captain; and he also approves of the first regiment of foot-guards being a regiment of grenadiers, and styled "The First or Grenadier Regiment of Foot-Guards." An alteration has also taken place in regard to the pensions allowed to wounded officers in favour of those who have served in the battle of Waterloo; and it is also ordered that henceforth every non-commissioned officer, trumpeter, drummer, and private man, who served in the battle of Waterloo, or in any of the actions which immediately preceded it, shall be borne upon the muster-rolls and pay-lists of their respective corps as "Waterloo Men;" and that every "Waterloo Man" shall be allowed to count two years' service in virtue of that victory, in reckoning his services for increase of pay, or for pension when discharged.

It is also ordered, that the lieutenants of cavalry and infantry, who had served more than five years as such, on the 18th of June 1815, or who may subsequently have completed that period of service, are to receive one shilling *per diem* for every day's service as lieutenant beyond five years, it being fully understood that the retrospect is, in no instance, to exceed two years. In like manner, the corporals and privates, distinguished as "Waterloo Men," are to receive the benefit of the two years' service retrospectively, in cases in which, by the addition of the two years, they would have completed their respective terms of service, on or previously to the 18th of June 1815, and the two years' service will, of course, be reckoned in all claims subsequently accruing.

Sir Charles Alten is honoured with the title of count, and the Hanoverian troops, who were present in the battle, may bear on their colours and uniform the word "Waterloo." Other regiments also that are particularly specified, are to have the word "Waterloo" in commemoration of their distinguished services, June 18th, 1815. The prince regent has commanded, that in commemoration of the brilliant and decisive victory of Waterloo, a medal shall be conferred upon every officer, non-commissioned officer, and soldier of the British army, present upon that memorable occasion. It is also appointed, that from the date of the battle of Waterloo, 18th June 1815, the pensions to officers and widows shall increase according to the officer's further advance.

It is a farther instruction with regard to the Waterloo grant, that lieutenants of cavalry and infantry, who had served more than five years on the 18th of June, are to receive one shilling *per day* for every day beyond five years' service, provided the retrospect be not beyond two years: non-commissioned officers and privates are also to benefit proportionately from the same retrospect. The charge for officers is to be made in their ordinary accounts; those for men distinct in a pay list supplementary, according to a prescribed form.

Prize-money was also granted by parliament to the army which served under the command of field-marshal his grace the duke of Wellington in the battle of Waterloo and cap-

ture of Paris. This was advertised in the London Gazette, June 21, 1817. Those shares that have not been claimed before the 24th of September 1817, may afterwards be received from the deputy treasurer of Chelsea hospital, if claimed within the period of six years.

The shares of each individual in the following classes are:

Commander-in-chief's proportion is estimated at	£61,000 0 0
Class 1. General officers	1,274 10 10 ³ / ₄
2. Field-officers and colonels	433 2 1 ³ / ₄
3. Captains	90 7 3 ³ / ₄
4. Subalterns	34 14 9 ¹ / ₂
5. Sergeants	19 4 4
6. Corporals, drummers, and privates	2 11 4

Notice has also been given in the Dutch, Flanders, and German papers, that his highness the prince of Waterloo, duke of Wellington, has given orders for the payment of the prize-money to all the allied troops, who fought under his command at Quatre Bras and Waterloo, at the taking of Paris.

His highness has fixed the proportions into classes as above. This distribution includes the Dutch, Belgic, Nassau, Hanoverian, and Brunswick troops.

The total amount of receipts for the Waterloo subscription to May 31, 1817, has been 518,288*l.* 9*s.* 11*d.* The total expenditure for payments and donations, and incidental charges, leaves a balance at the bankers 18th of June 1817 of 1,222*l.* 13*s.* 5*d.*

Statement of the appropriation is as follows:

<i>Annuities granted for Life.</i>	
To the widows of officers, non-commissioned officers, and privates killed	£9,594
To the wounded non-commissioned officers, and privates totally disabled	1,649
To dependent relatives	540
Amount of annuities for life	11,783
<i>Annuities granted for limited Periods.</i>	
To the children of officers, non-commissioned officers, and privates	8,314
To orphans	895
Amount of annuities for limited periods	9,209
Total amount of annuities	20,992

<i>Voted in Money.</i>	
To the wounded officers, non-commissioned officers, and privates	71,126
To the parents and dependent relatives of officers, non-commissioned officers, and privates killed, leaving no widows or children	28,577

<i>To the Foreign Troops, viz.</i>	
Prussians, Brunswickers	45,000
Hanoverians, and Netherlanders	17,500
Additional for the exclusive benefit of their orphans rendered such by the campaign of 1815	62,500
Total amount voted in money	162,203

A considerable subscription, amounting to 3905*l.* 14*s.* 9*d.* received

received from Demerary, has been lately announced, February 24, 1818.

On the second anniversary of the battle of Waterloo, the noble structure of the bridge over the Thames from Surrey to the site of the Savoy, was first opened for public accommodation; and with a view of commemorating the ever-memorable victory of Waterloo, its name was changed from that of the "Strand Bridge," to the more dignified and triumphal appellation of "Waterloo Bridge." The ceremony was conducted with great dignity and splendour.

This bridge exhibits a very striking display of the eminent abilities and taste of Mr. Rennie, the engineer, as well as of the liberality of the proprietors, who have provided the funds necessary for its construction. Its situation is judiciously selected, as, independently of the advantage which commerce and the convenience of personal intercourse may derive from it, it gives the grandest view we have of the river in its beautiful meander, displays the rising crescent of buildings on the north side, and brings out Somerset Terrace in the most favourable way; while on the south it opens the beautiful prospect of the Surrey hills.

The following are some detailed particulars of the bridge, which is constructed of Cornish granite; the balustrades are of granite from Aberdeen.

Dimensions of the Bridge.

	Feet.
The length of the stone bridge within the abutments	1,242
Length of the road supported on brick arches on the Surrey side of the river	1,250
Length of the road supported on brick arches on the London side	400
Total length from the Strand, where the building begins, to the spot in Lambeth where it falls to the level of the road	2,892
Width of the bridge within the balustrades	42
Width of pavement or foot-way on each side	7
Width of road for horses and carriages	28
Span of each arch	120
Thickness of each pier	23
Clear water-way under the nine arches, which are equal, 120 ft. each	1,080
Brick arches on the Surrey side	40
Ditto on the London side	16
Granite ditto for the water-course	9
Total number of arches from the Strand to the Lambeth level	65

In building the arches, the stones (some of which weigh upwards of six tons) were so accurately jointed and carefully laid, that upon the removal of the centres, none of the arches sunk more than an inch and a half. In short the excellency of the workmanship vies with the beauty of the design, and with the skill and arrangement, to render the "Bridge of Waterloo" a monument of the public spirit, taste, and glory of the age, of which the metropolis, and the British empire, have abundant reason to be proud.

We shall close our account of the battle of Waterloo, with stating a fact not unworthy of being recorded. The states-general desiring to give to his royal highness the prince of Orange a testimony of the national gratitude, for the bravery which he employed, as well in the defence of the position of Quatre Bras as at the battle of Waterloo, have proposed to his majesty, to purchase at the expence of the State a palace, situated in the city of Brussels, which, after being properly furnished, may be given in full property to his royal highness the hereditary prince, as well as the park of Toweuren, in the forest of Soigné, with a hunting-seat;

and that these estates be transferred to the prince of Orange, free of all charges and expence. His majesty approved of this proposal. See *Battle of Waterloo, &c.* 2 vols. 8vo. London, 1817.

WATERMEN are such as row in boats, or ply on the river Thames, ultimately subject to the direction and government of the lord-mayor of London, and court of aldermen, who settle their fares, and, as well as other justices of peace, have authority to hear and determine offences, &c.

The names of watermen are to be registered; and their boats must be twelve feet and a half long, and four and a half broad, or be liable to forfeiture; and watermen, taking more than the fares assessed, shall forfeit 40s., and suffer half a year's imprisonment; and refusing to carry persons for their fare, shall be imprisoned for twelve months. None shall ply on the river, but such as have been apprentices to watermen for seven years. 2 & 3 P. & M. cap. 16. 29 Car. II. cap. 7.

The lightermen and watermen constitute a company; and the lord-mayor and aldermen yearly elect eight of the latter, and three of the former, to be rulers, and the watermen choose assistants; the rulers and assistants being empowered to make rules, which are required to be observed, under penalties. The rulers on their court-days shall appoint forty watermen to ply on Sundays, for carrying passengers across the river, who pay them for their labour, and apply the overplus to the poor decayed watermen; and no persons are allowed to travel on a Sunday with boats, unless they are licensed and allowed by a justice, on pain of forfeiting 5s. 11 & 12 W. III. cap. 21.

No apprentice shall take upon him the care of a boat, till he is sixteen years of age, if a waterman's son, and seventeen, if a landman's, unless he hath worked with some able waterman for two years, under the penalty of 10s.; and if any person, not having served seven years to a waterman, &c. row any boat in the river Thames for hire, he shall forfeit 10l., gardeners' boats, dung-boats, fishermen's, wood-lighters, western barges, &c. excepted. No apprentice is to be taken under fourteen years, who shall be bound for seven years, and enrolled in the book of the watermen's company, on pain of 10l. No tilt-boat, row-barge, &c. shall take more than thirty-seven passengers, and three more by the way; nor any other boat above eight, and two by the way, on forfeiture of 5l. for the first offence, and 10l. for the second, &c. And in case any person be drowned, where a greater number is taken in, the waterman shall be deemed guilty of felony, and transported. 10 Geo. II. cap. 31.

Tilt-boats used between London-bridge and Gravesend shall be fifteen tons, and the other boats three tons. Rulers of the watermen's company are required to appoint two officers, one at Billingsgate at high-water, and another at Gravesend, to ring a bell for the tilt-boats, &c. to put off; and those which do not immediately proceed with two sufficient men, shall forfeit 5l. The fares of watermen, assessed by the court of aldermen, are, from London-bridge to Lime-house, Ratcliffe-crofs, &c. for oars 1s., and scullers 6d.; Wapping-dock, Rotherhithe-church stairs, &c. for oars 6d., and for scullers 3d.; from either side of the water above the bridge to Lambeth and Vauxhall, for oars 1s., and scullers 6d. For all the stairs between London-bridge and Westminster, oars 6d., and scullers 3d.

WATERS, among *Farriers*, the name given to a dis-temperature of horses. See *WATERY SORES*.

WATERSAY, in *Geography*, one of the Western islands of Scotland, about one mile south from South-Uist, from which it is separated by a channel, called "Chifamul Bay." This island is about three miles long, and one broad. N. lat. 56° 54'. W. long. 7° 30'.

WATERTIGHT STUFF denotes clay, or any other tenacious and compact soil, which will hold water.

WATERTOWN, in *Geography*, a town of Massachusetts, in the county of Middlesex, containing 1531 inhabitants; 7 miles W.N.W. of Boston.—Also, a town of Connecticut, in the county of Litchfield, containing 1714 inhabitants; 26 miles N.N.W. of New Haven.

WATERTOWN, a post-township of New York, the capital of Jefferson county, and a place of deposit for the military stores of the state of New York. It lies near the mouth of Black river, about 80 miles N.W. of Utica, and was first created into a town in March 1810, from a part of Mexico, then in Oneida county, and comprised also Rutland and Hounsfield. Its extent is about six miles square. The inhabitants are principally emigrants from the eastern states. Here are about 200 dwelling-houses, eight school-houses, a court-house and gaol, together with a lodge and arsenal for military stores. Here are also eight grist and saw-mills, one paper-mill, one wool-carding machine, five distilleries, two breweries, a printing-office and weekly paper, a small air-furnace, and many common mechanics. It promises to be a place of much business. Pot and pearl ashes are manufactured in abundance, and sent in boats to Montreal. By the census of 1810, the population consists of 1849 persons; and here are 308 senatorial electors.

WATERTOWN, or *Jefferson Village*, is a flourishing post-village of Watertown, in Jefferson county, on the south bank of Black river, four miles from Brownville, and at the same distance from navigable water communicating with lake Ontario. The village contains about 50 dwelling-houses, some of which are elegant. In its vicinity are a quarry of good building lime-stone, clay, and sand. Pine and other timber are plentiful.

WATERVILLE, a town of the district of Maine, and county of Kennebeck, containing 1314 inhabitants.

WATERVLIET, a large township of New York, in the north-east corner of Albany county, 6 miles N. of Albany; extending 10 miles along the Mohawk, and 6½ miles along the Hudson, and having an area of about 52 square miles, exclusive of several islands in the Hudson. Much of the land is poor and barren, and the population is very unequally distributed. Along the Hudson are some fine flats, and in many places the river-hills are moderately steep, and afford good farming lands. The interior abounds with sandy ridges, some marshes, and wet land, wooded with pine and a variety of dwarf shrubbery, of little value. In this township are two small villages, *viz.* Washington, five miles north of Albany, and Gibbon's Ville, opposite Troy, six miles. The Cahoos, which are the principal falls of the Mohawk, are between Watervliet and Halfmoon, in Saratoga county. The whole river Mohawk descends in one sheet at high water, about 70 feet; and below the falls the spreading branches form islands, which are attached to this town: these are Haver island, Van Schaick's island or Cahoos island, and Green island. In this town are 1092 white males, 1070 white females, 128 slaves, and 75 other persons; in all 2365; and 215 senatorial electors. The settlement of the people called "Shakers" lies in the north-west part of this town, at a place called Niskayuna, 8 miles N.W. of Albany. They have a house of worship, and the village contains about 150 houses. A manufactory of iron screws has lately been erected on the Mohawk, near Cahoos bridge.

WATERVLIET, a town of Flanders; 12 miles E. of Sluys.

WATERY HEAD. See **HYDROCEPHALUS**.

WATERY Humour. See **AQUEOUS** and **HUMOUR**.

WATERY Lands, in *Agriculture*, all such as are largely impregnated with and retentive of moisture or wetness.

Wherever water rests much upon lands, it sours them, and destroys the finer herbage; the remaining plants being made to become coarse and strong, but mostly unpalatable, and of little value for stock. They should, of course, have the superabundant water removed from them, and then be improved by suitable substances applied as manures, and by other means, such as being flooded, in some cases.

By such methods, according to the nature of their wetness, such lands may mostly be brought into a good state of improvement. See **BOG**, **FEN**, **MORASS**, **MARSH**, and **SWAMP**; also the lands of their several natures.

WATERY Poke, a name sometimes given to a disease in sheep, from their having a sort of poke or bag hanging below the top of their throats, supposed to be caused by water. See **SHEEP** and **ROT**.

WATERY Sores, diseases of the legs and pasterns of horses and some other animals, in which there are watery swellings and sores, which discharge an acrid watery fluid. They mostly arise from bad feeding, and improper management in dressing and the use of exercise.

The cure will commonly be effected by giving strengthening remedies, with calomel and squills in moderate doses, and by the gradual use of elastic bandages to the parts.

WATFORD, in *Geography*, a market-town in the hundred of Cashio, and county of Hertford, England, is 8 miles S.E. from St. Alban's, 20 miles W.S.W. from the county-town, and 14 miles N.W. from London. Previous to the Conquest, Watford formed part of Cashio, and under that appellation was given by king Offa to the abbey of St. Alban's, to which it continued attached till the time of the dissolution, when the stewardship of this and other adjacent manors was given to John, lord Ruffel. James I., in the seventh year of his reign, granted Watford to the lord chancellor Eger-ton, in whose descendants, the dukes of Bridgewater, it remained vested till about the year 1760, when it was purchased by the then earl of Essex, and is now the property of the present earl. The town consists principally of one street; the houses being ranged on the sides of the high road, and extending in a north-westerly direction rather more than a mile. The buildings are chiefly of brick, and many of them very respectable. The police is under the direction of the resident and neighbouring magistrates. A market, which is now held on Tuesdays, was granted to the abbots of St. Alban's for Watford by Henry I.; and Edward IV. gave them liberty to hold two annual fairs, which are now increased to four. The market-house is a long building, rough-cast above, and supported on wooden pillars beneath. Corn is sold here in very large quantities; and the number of cattle, sheep, calves, and hogs, is proportionable. Employment for the labouring classes is chiefly derived from agriculture; but an additional source is furnished by the throwing of silk, three silk mills having been established in or near the town. The parish of Watford comprehends, with the town, the hamlets of Cashio, Levesdon, and Oxhey. In the population return in the year 1811, the number of inhabitants was stated to be 3976, occupying 766 houses. The church, a very spacious edifice, consists of a nave, three aisles, and a chancel; with a massive embattled tower at the west end, about 80 feet high. The church contains several fine monuments, among which are two by Nicholas Stone. At the south side of the church-yard is a free-school, founded and endowed in the year 1704, by Mrs. Elizabeth Fuller, for the education and clothing of forty boys and twenty girls: the government is vested in nine trustees, chosen out of the principal inhabitants of the town. Here are also eight alms-houses, for the maintenance of so many poor widows.

About one mile north-west of the town is *Cashbury*, the seat of the earl of Essex. The mansion is a spacious edifice, situated in an extensive and well-wooded park, through which flows the river Gade; and to which is the line of the Grand Junction Canal. The house was originally begun in the time of Henry VIII. by Richard Morison, esq., and completed in the style of that age by his son, sir Charles Morison. It has since been greatly altered and improved, particularly under the direction of the present noble owner, and contains a number of elegant apartments, together with a kind of cloister, the windows of which have been recently ornamented with painted glass, executed in a very superior style. In its general appearance, the whole mansion, with its offices, has the character of a monastic dwelling. The rooms are adorned with numerous portraits, and other pictures of the first degree of merit. The park is between three and four miles in circumference, and affords rich scenery and noble timber; the pleasure-grounds and gardens are extensive, and have lately undergone some judicious alterations. A particular description of this splendid seat, by Mr. Britton, is contained in Havell's "Views of Gentlemen's Seats," &c. which also contains a print of it.—Salmon's History of Hertfordshire, fol. 1728. Beauties of England and Wales, vol. vii. Hertfordshire, by E. W. Brayley, 1808.

WATH, in *Rural Economy*, a term often used provincially to signify a ford.

WATHULT, in *Geography*, a town of Sweden, in the province of Smaland; 47 miles W.N.W. of Wexio.

WATKIN'S POINT, a cape on the S.W. coast of Maryland, in the Chesapeake. N. lat. 37° 59'. W. long. 76°.

WATLING'S ISLAND, one of the Bahama islands, about 18 miles long, and 4 broad. N. lat. 23° 50'. W. long. 74° 16'.

WATLING-Street, in *Roman Antiquity*. See WAY.

WATLINGTON, in *Geography*, a small market-town in the hundred of Pirton, and county of Oxford, England, is situated between the two high roads leading from London to Oxford, about half a mile N. by W. from the Ike-neild-street, at the distance of 5 miles S. from Tetworth, 15 miles S.E. from Oxford, and 46 miles W. by N. from London. The streets are narrow, and the houses, with a few exceptions, mean and ill built. There is no staple manufacture of any consequence: the making of lace, however, prevails to some extent, and forms the chief employment of the labouring females. A school has been formed expressly for the purpose of teaching this art, and is usually attended by from forty to fifty pupils. The town is watered on the south side by a brook, rising in the vicinity, which now works, within two miles from its source, four corn-mills. A weekly market is held on Saturdays, which was originally granted to Roger Bigod, earl of Norfolk, in the reign of Richard I. But this market is thinly attended; and the business of the day is invariably conducted in the parlours of the principal inn. Here are likewise two annual fairs. In the centre of the town is the market-house, a substantial building, erected by Thomas Stonor, esq. in the year 1664: he also founded and endowed a grammar-school for ten boys; according to the will of the donor, the master was to be a graduate of one of the universities; but imperative circumstances have caused this article to be dispensed with: four boys have been added to the original number, and the whole are taught in a commodious room above the market-house, in which are likewise held the courts leet and baron of the manor. The magistrates hold a petty sessions once in a fortnight during the winter, but in summer not so often. According to the population return of the year 1811, this town

then contained 239 houses, the number of inhabitants being 1150, which was a decrease of 156, since the enumeration of the year 1801. The church is a respectable ancient building, situate N.W. of the town: in the chancel are several neat monuments, and a handsome burial-place of the Horne family. Lands and tenements have been left by will for the repairs of the church, without any parish-rate for that purpose; and there have also been considerable sums bequeathed for the use of the poor. Previous to the Reformation, the abbot and canons of Olney were patrons, to whom the church was appropriated in 1263, by the bishop of Lincoln. In this parish was anciently a chapel, founded by the lord of the manor of Watcomb; but on a complaint made by the abbot and canons of Olney, pope Urban III. dissolved it: no traces can now be discovered of the site occupied by this structure. Wesleyan Methodists and Baptists have each a place of worship in the town; but the number of these societies is comparatively small. The Methodists were established here during the life of John Wesley, who occasionally preached in the open street: a substantial meeting-house has lately been erected, but not more than thirty persons are in the habit of attending. The Baptists are scarcely so numerous; and their meetings are held in a very humble building. The manor of Watlington was given by Henry III. in 1231, to his brother Richard, earl of Cornwall. By Edward II. it was granted to Piers Gaveston. On his disgrace it reverted to the crown, and was given by Edward III. to sir Nicholas De la Becke, who obtained permission, in 1338, to build a spacious castle, some traces of which were discernible within the last century. The building stood on a slightly elevated spot to the south-east of the church, and it may yet be perceived that the structure was encompassed by a moat. King Charles I. granted the manor, in 1628, to four citizens of London, who sold it in the following year. Soon after this period it became so divided and parcelled out, that in the year 1664 there were about fifty persons participating in the manorial rights; and previous to the enclosure of the parish, which took place in 1809, the shares of the manor were sixty-four in number.

On *Britwell-hill*, about a quarter of a mile east of the Ike-neild-street, some remains of trenches point out the site of an ancient encampment.

Within half a mile from Watlington is one of the most complete agricultural establishments to be found in the county. The whole of the very extensive farm-yard is encompassed by buildings covered with slate, and presents the spectacle of a new and handsome village. This noble range was erected under the immediate inspection of William Hayward, esq., and was completed in the space of one year. His primary object appears to have been to produce utility on the simplest and most scientific plan.

About a mile to the north of Watlington is Pirton, an inconsiderable village, though it gives name to the hundred. Near Pirton is *Shirbourn-Castle*, the seat of the earl of Macclesfield. A castellated edifice was first erected on this spot in the fourteenth century by sir Warner de l'Isle. The castle and manor were purchased at the beginning of the eighteenth century by Thomas, earl of Macclesfield. The building forms an oblong square, and is encompassed by a broad and deep moat, over which are three draw-bridges; the chief entrance is guarded by a portcullis: at each angle of the edifice is a circular tower. The interior is disposed in a style of modern elegance and comfort that contains no allusion to the external character of the structure, except in one long room fitted up as an armoury, and containing coats of mail, shields, tilting-spears, and offensive arms of a modern as well as ancient date. A park of about sixty acres is attached

attached to the mansion.—Beauties of England and Wales, vol. xii. Oxfordshire. By J. N. Brewer, 1813.

WATO, a town of Sweden, on an island in the Baltic, near the coast of the province of Upland; 10 miles E.N.E. of Nortelge. N. lat. 59° 54'. E. long. 18° 43'.

WATOLMA, a town of Sweden, in the province of Upland; 10 miles N. of Upfal.

WATRAP, a town of Hindooftan, in Madura; 33 miles S.W. of Madura.

WATSCH, or VATSCHE, a town of the dutchy of Car-niola; 16 miles S.E. of Stein.

WATSNESS, a cape on the west coast of the island of Shetland. N. lat. 60° 19'. W. long. 2° 6'.

WATSON, ROBERT, D.D., in *Biography*, a Scottish historian, was born at St. Andrew's about the year 1730, commenced his course of education for the ministry at the school and university of St. Andrew's, and with singular assiduity prosecuted his studies at the university of Glasgow, and also in that of Edinburgh. He paid particular attention to grammar and eloquence, and with the advice of lord Kaimes, delivered a course of lectures on these subjects, which gained the approbation of Mr. Hume, and other men of genius and learning. Having failed in his endeavours to supply a vacancy in one of the churches of St. Andrew's, he was soon after made professor of logic, and by a patent from the crown, professor of rhetoric and belles lettres. In his lectures on logic and metaphysics, he deviated from the old plan of syllogisms, modes, and figures, and introduced substantial improvement by furnishing his pupils with an analysis of the powers of the mind, and by leading them to investigate the various kinds of evidence, of knowledge or truth. His history of Philip II. advanced his reputation during the period of his life; and it was farther enhanced by his history of Philip III., which was published after his death; of which latter he only wrote the first four books, the other two being supplied by Dr. William Thomson, the editor, at the desire of the guardians of his children. He succeeded Tulideph as principal of the university by the interest of the earl of Kinnoul; but his death, in 1780, soon deprived him of this honour. By his wife, who was daughter of Mr. Shaw, professor of divinity in St. Mary's college, St. Andrew's, he had five daughters, who survived him. Gen. Biog.

WATSON, RICHARD, an English prelate, eminently distinguished by his talents, acquirements, and character, was born at Haverham, in Westmoreland, in August 1737. He was the descendant of an ancient family, deriving its remote origin from Scotland, and occupying, for several generations, a small estate at Hardendale, near Shap, where his father was born in the year 1672. In 1698 his father was appointed head master of Haverham-school, which he conducted with great reputation for nearly forty years. Among other pupils who enjoyed the benefit of his instruction, we may mention Ephraim Chambers, the well-known author of the Dictionary of Arts and Sciences (see his article), Mr. Preston, afterwards bishop of Ferns, in Ireland, and the subject of this memoir. To this school belonged two exhibitions, (now of 50*l.* a year each,) one to Trinity college, in Cambridge, and the other to Queen's college, Oxford; the former of which was enjoyed by Mr. Preston, and afterwards by his school-fellow, Mr. Watson. In the year 1788, these two scholars, being then bishops, testified their regard for the place of their education by repairing the school-house, and by affixing to it a Latin inscription, expressing their respect for the memory of its pious founder, and of Mr. Watson's father. To his mother also Mr. Watson pays a tribute of grateful and affectionate

remembrance, describing her as a charitable and good woman, to whom he was indebted for imbuing his young mind with principles of religion, which never forsook him; and observing more generally, that "the care of the mother precedes that of the school-master, and may stamp upon the *rafa tabula* of the infant mind, characters of virtue and religion which no time can efface." Soon after the death of his father, in November 1753, Mr. Watson was sent to the University, and admitted a sizar of Trinity college, in Cambridge, on the 3d of November, 1754. Apprized that his patrimony, which was 300*l.*, would be barely sufficient to defray the charges of his education, and having no expectations from any of his relations, he determined to fabricate his own fortune, and applied with assiduity and ardour to his academic studies. Before he had been six months at college, a circumstance occurred which indicated his talents for metaphysical disquisition, and which contributed in no small degree to his reputation in this department of science. As he attended the college-lectures, which were then delivered to the under-graduates in the hall, immediately after morning-prayers, during term-time, he was asked by Mr. Brocket, the head lecturer, whether Clarke had demonstrated the absurdity of an infinite succession of changeable and dependent beings? to which question he replied *non*; and being asked his reasons for so thinking, he stammered out, as he says, in barbarous Latin, "that Clarke had enquired into the *origin* of a series, which, being from the supposition *eternal*, could have no origin; and into the *first* term of a series, which, being from the supposition *infinite*, could have no first." This circumstance was recollected four years afterwards, when he took his bachelor's degree, and laid the foundation of his acquaintance with Dr. Law, then master of Peterhouse, and reckoned one of the best metaphysicians of his time; from which he derived, as he acknowledges, much knowledge and liberality of sentiment in theology. Not satisfied with his rank of sizar, he aspired to a scholarship, and succeeded in obtaining it, on the 2d of May, 1757, a year before the usual time. Thus advanced in rank, his expences increased, but they were more than counterbalanced by the advantage attending it. Dr. Smith, who was then master of the college, took occasion to nominate him to a particular scholarship (lady Jermy'n's); and at the same time recommended Saunderfon's Fluxions, just published, and some other mathematical books, to his perusal; thus, as he says, "giving a spur to my industry, and wings to my ambition." At this time he had resided in college two years and seven months, without leaving it for a single day; and during this period, he had acquired some knowledge of Hebrew, improved himself greatly in Greek and Latin, made considerable proficiency in mathematics and natural philosophy, and studied with much attention Locke's Works, King's book on the Origin of Evil, Puffendorf's Treatise "De Officio Hominis et Civis," and some other books on similar subjects. Conceiving himself entitled to some degree of relaxation, he set out, in May, 1757, on a visit to his elder and only brother at Kendal, who was the first curate of a new chapel erected there, and to the building of which he had liberally contributed. This brother lived freely, spent his fortune, injured his constitution, and died when the subject of our memoir was about the age of 33. With the affection of a brother and singular liberality, he paid his debts, to the amount of almost his whole property. In the beginning of September he returned to college, with a purpose to make his alma mater the mother of his fortunes. He was then only a "junior sopher;" but such was his reputation, that he was solicited to become private tutor to Mr. Luther and Dr. Strachey. From the

time in which he undertook this charge he was employed for thirty years, and as long as his health lasted, in instructing others, without much instructing himself, as he suggests, and in presiding at disputations in philosophy or theology, from which, after a certain time, he derived little intellectual improvement. Addicted, whilst an under-graduate, to associate with those whom collegians call the best company; such as idle fellow-commoners, and other persons of fortune: he soon perceived that he was pursuing a mistaken course: and this conviction was more sensibly felt, when he often saw, on his return home at one or two in the morning, from some of his evening festivities, a light in the chamber of a fellow-student of the same standing with himself. His jealousy was thus excited, and the succeeding day was always devoted to hard study; nor would he allow himself the leisure for dinner. In his solitary walks he prosecuted the study of mathematics and philosophy without book, or pen and paper; and went through tedious and intricate demonstrations by the mere exercise of his mental powers. These walks were so frequent, that among those who did not know how he was employed, he incurred the charge of being a lounge; but the sequel of his history sufficiently proves the injustice of the charge.

Whilst abstract studies occupied his chief attention, he did not neglect other pursuits. Every day he imposed upon himself the task of composing a theme in Latin or English. Among the first of his compositions of this kind, the subject of that written in English was "Let tribunes be granted to the Roman people," and that of the Latin was "Sociis Italicis datus Civitas:" the subjects of both were suggested to him by a perusal of Vertot's "Roman Revolutions;" and to his account of this incident he adds, "Were books of such kind put into the hands of kings during their boyhood, and Tory-trash at no age recommended to them, kings in their manhood would scorn to aim at arbitrary power through corrupted parliaments." He also introduces this reflection on the choice of his subjects: "They shew that a long commerce in the public world has only tended to confirm that political bent of my mind in favour of civil liberty, which was formed in it before I knew of what selfish and low-minded materials the public world was made." In the course of Mr. W.'s classical reading, to which he devoted the afternoon, whilst the morning was occupied by mathematics, he informs us, that Demosthenes was the orator, Tacitus the historian, and Persius the satirist, whom he most admired. At an early period of his life, Mr. W. inclined to the opinion which has in later times been more prevalent, that the soul is not a distinct substance from the body; though he professes not to have troubled himself much with perplexing disquisitions concerning liberty and necessity, matter and spirit; shewing, however, on all occasions, his faith in Christianity, as founded on testimony, and more especially on the testimony concerning the resurrection of its divine founder; and his belief of a future state of retribution and immortality. His speculations on matter and spirit are not likely, in our judgment, to illumine the darkness, and to resolve the difficulties that involve this subject. As to the story, recorded in the French Encyclopædia (art. *Mort*), of a man who came to life after having been six weeks under water, we cannot help considering it as fabulous; but whether it be true or false, it appears to us to afford little satisfaction with regard to the question in dispute. Nor does his reasoning about the essential properties of extension, solidity, mobility, divisibility, and inactivity, as common properties, belonging equally to a table, tree, oyster, and man, and the addition of life to the matter of the tree, of life and perceptivity to that of the oyster, and to that of

the man, life, perceptivity, and thought, seem to have given very great satisfaction to himself. "Whether life can exist without perceptivity," he says, "or perceptivity without thought, are subtle questions, not admitting perhaps, in our present state, a positive and clear decision either way. Physical and metaphysical difficulties present themselves on every subject, and ultimately baffle all our attempts to penetrate the darkness in which the divine mind envelopes his operations of nature and grace."

In January 1759, Mr. W. took his degree of bachelor of arts. In the first year of his being moderator, he introduced an alteration in the mode of obtaining this degree, which has been continued ever since. "At the time of taking it, the young men are examined in classes, and the classes are now formed according to the abilities shewn by individuals in the schools. By this arrangement, persons of nearly equal merits are examined in the presence of each other, and flagrant acts of partiality cannot take place. Before this alteration was made, they were examined in classes, but the classes consisted of members of the same college, and the best and the worst were often examined together." In the first year of his being moderator, Mr. Paley, afterwards so well known, and a Mr. Frere of Norfolk, were examined together; and Mr. Paley, being Mr. Frere's superior, was made senior wrangler, though it was reported that the grandfather of Mr. Frere had proposed to give 1000*l.* if he were admitted to this honour. This gentleman afterwards candidly acknowledged that he deserved only the second place; and this declaration was obviously the result of their having been examined together. One of the questions proposed by Mr. Paley for his act was "Æternitas pœnarum contradicit Divinis attributis." This question, though accepted by Mr. W., occasioned an alarm; but in order to allay all disquieting apprehensions, Mr. P. was allowed to put in *non* before *contradicit*, and the alarm subsided. This, however, says Mr. W., is a subject of great difficulty. "It is observed, on all hands, that the happiness of the righteous will be, strictly speaking, everlasting; and I cannot see the justness of that criticism which would interpret the same word in the same verse in a different sense. (Matt. xxv. 46.) On the other hand, reason is shocked at the idea of God being considered as a relentless tyrant, inflicting everlasting punishment which answers no benevolent end. But how is it proved that the everlasting punishment of the wicked may not answer a benevolent end, may not be the means of keeping the righteous in everlasting holiness and obedience? How is it proved, that it may not answer, in some other way unknown to us, a benevolent end in promoting God's moral government of the *Universe*?"

In October 1760, Mr. W. was elected a fellow of Trinity college, although by that appointment he was put over two of his seniors of the same year; and in the following November became assistant tutor to Mr. Backhouse. Soon after this he declined accepting the curacy of Clermont; and he also relinquished his design of going out as chaplain to the factory at Bencoolen. "You are far too good," said the master of the college to him, "to die of drinking punch in the torrid zone." Afterwards he reflected with gratitude and self-complacency on his disappointment of an opportunity of becoming an Asiatic plunderer. "I might not," he says, "have been able to resist the temptation of wealth and power, to which so many of my countrymen have yielded in India."

At the commencement of 1762 he took his degree of M.A., and in the following October was made moderator for Trinity college. In his "Memoirs," he recites the questions which were at that time the subjects of scholastic exercises,

ercises, and from their nature and variety he justly infers the importance of these exercises.

In February 1764 an occasion was afforded him of manifesting his friendly attachment to Mr. Luther, one of the members for Essex, who had been formerly his pupil, and his disinterested anxiety for his happiness. Having heard that he had separated from his wife, and was hastily gone abroad, he immediately prepared to seek him, and to impart to him, if possible, some consolation. Although he had no money, and could not speak a word of French, he determined on his journey; and having borrowed 50*l.*, and provided a French and English Dictionary, he posted to Dover, and hastened to Paris, where he found his disconsolate friend. After twelve hours stay at Paris, he returned to England; and having crossed the channel four times, and travelled 1200 miles in very bad weather within a fortnight, he brought his friend back to his country and his family. Of Mr. Luther, he says that "he was a thorough honest man, and one of the friends I ever loved with the greatest affection."

In November 1764, he was unanimously elected by the senate to succeed Dr. Hadley, as professor of chemistry; and though at this time he knew nothing of chemistry, he procured an operator from Paris, and immured himself in his laboratory, so that in 14 months from his election he read a course of chemical lectures to a very full audience, and another in November 1766. For the fourth time he was made moderator in October 1765, and in 1766 made his last speech in Latin to the senate. Besides other improvements in the university education, which he had proposed on former occasions, he now recommended the institution of public annual examinations, in prescribed books, of all the orders of students. In 1774 this subject was revived and enforced by Mr. Jebb. The design was unequivocally approved by the chancellor of the university, the duke of Grafton. After a long discussion of the subject, the regulations drawn up by the syndics were proposed to the senate, and were rejected by the "Non Regent House," 47 against 43. In 1764 application was made for a stipend to the professor of chemistry; and after considerable delay, 100*l.* a year was obtained: and this grant paved the way for similar stipends to the professors of anatomy, botany, and common law. In October 1767, Mr. Watson succeeded Mr. Backhouse as head tutor in Trinity college, and, for the short period during which he retained the office, discharged its duties with conscientious diligence. "In this," he says, "and the two following years, I read chemical lectures to very crowded audiences, in the month of November. I now look back with a kind of terror at the application I used in the younger part of my life. For months and years together, I frequently read three public lectures in Trinity college, beginning at 8 o'clock in the morning; spent four or five hours with private pupils, and five or six more in my laboratory, every day, besides the incidental business of presiding in the sops schools."

In 1768 he composed and printed his "Institutiones Metallurgicæ," and about the same time presented to the Royal Society a paper on the solution of salts, and was elected a fellow of that society. In the following year he published his Assize Sermon, which he dedicated to Mr. Luther. Upon the vacancy in the office of regius professor of divinity, occasioned in October 1771 by the death of Dr. Rutherford, Mr. Watson proposed to become a candidate; but he was then neither bachelor nor doctor in divinity; and without being one of these, he could not be admitted as a candidate. Prompt, however, in the execution of all his measures, though he had only seven days for the

accomplishment of his object, he obtained the king's mandate for a doctor's degree, and was created a doctor on the day previous to that appointed for an examination of the candidates. The subjects on which he was to write were, the reconciliation of the genealogies in Matthew and Luke, and the interpretation of the passage, "What shall they do that are baptized for the dead?" 1 Cor. xv. 29. He was also appointed to read a Latin dissertation on Gen. x. 32.

At length he was unanimously elected, having, as he says, by hard and incessant labour for 17 years, attained, at the age of 34, the first office for honour in the university, and, exclusive of the mastership of Trinity college, he made it the first for profit; having advanced it from 330*l.* a year to at least 1000*l.* Having been promoted to this honourable and important office, he devoted himself, with his accustomed resolution and perseverance, to the study of divinity; making the Bible the object of his investigation, and feeling no concern about the opinions of councils, fathers, churches, bishops, or other men, as little inspired as himself. Although he was called by the master of Peterhouse, *αυτοδιδάκτος*, the self-taught divine; and though the professor of divinity had been nicknamed "Mallens Hæreticorum," he professes that his mind was wholly unbiassed; without prejudice against or predilection for the church of England; and actuated only by a sincere regard for the church of Christ, and an insuperable objection to every degree of dogmatical intolerance. "I never troubled myself," thus he proceeds, "with answering any arguments which the opponents in the divinity schools brought against the articles of the church, nor ever admitted their authority in decision of a difficulty. But I used, on such occasions, to say to them, holding the New Testament in my hand, 'En sacrum codicem! Here is the fountain of truth; why do you follow the streams derived from it by the sophistry, or polluted by the passions of men? If you can bring proofs against any thing delivered in this book, I shall think it my duty to reply to you: articles of churches are not of divine authority; have done with them; for they may be true, they may be false; and appeal to the book itself.' This mode of disputing gained me no credit with the hierarchy; but I thought it an honest one, and it produced a liberal spirit in the university."

About the close of the year 1771 our author printed an Essay on the subject of chemistry, which was dispersed among some few friends; but it was unjustly charged by the authors of the "Journal Encyclopedique," with favouring the "Système de la Nature." The author remonstrated, and the periodical journalists made an apology. In the following year Dr. Watson published two letters to the members of the house of commons, under the feigned name of a Christian Whig, the second of which was inscribed to Sir George Savile. In 1773, upon maturely weighing the question concerning the abstract right which a national church may claim of requiring subscription to human articles of faith from its public ministers, he published "A brief State of the Principles of Church Authority," which he delivered as a charge to the clergy of his diocese, in June 1813. In this tract it is maintained, that every church has a right of explaining to its ministers what doctrines it holds; and of permitting none to minister in it, who do not profess the same belief with itself. With respect to another question, *viz.* whether the majority of the members of any civil community have a right to compel all the members of it to pay towards the maintenance of a set of teachers appointed by the majority to preach a particular system of doctrines, this may admit a serious discussion. Our author once thought the majority had this right in *all* cases, and he afterwards apprehended that they have it in *many*. But a case may happen,

happen, in which the established religion of a country may be the religion of a minority of the people, that minority at the same time possessing a majority of the property, out of which the ministers of the establishment are paid; and if this should occur, our author seems to be undecided in his judgment. His sentiments as to the expediency of requiring from the ministers of the established church a subscription to the present articles of religion, or to any human confession of faith, further than a declaration of belief in the scriptures, as containing a revelation of the will of God, may be collected from his two pamphlets, subscribed "A Christian Whig," and "A Consistent Protestant."

In adverting to these tracts, our author reflects with satisfaction on the coincidence of his sentiments, on many points civil and religious, with those of bishop Hoadly, though he has been sarcastically and injuriously called "A republican bishop."

On the 21st of December 1773, Dr. Watson married the eldest daughter of Edward Wilson, esq. of Dallum Tower, in Westmoreland; and the connection was a source of uninterrupted satisfaction and felicity. Having obtained, by the interest of the duke of Grafton with the bishop of St. Asaph, a sinecure in Wales, he exchanged it, by the same interest, on his return to Cambridge, for a prebend of Ely; and this favour was granted, though the duke and Dr. Watson held different political opinions. They afterwards differed also in their religious sentiments; the duke having avowed himself an Unitarian. Referring to him under this denomination, Dr. Watson, with laudable liberality, declares, "that he is happy in seeing a person of his rank professing with intelligence and sincerity Christian principles. If any one thinks that an Unitarian is not a Christian, I plainly say, without being myself an Unitarian, that I think otherwise."

Dr. Watson's political principles are well known. From his earliest youth to his dying day he was a Whig, in that sense of the term which is well understood, and need not here be explained. In 1776 it came to his turn to preach the restoration and accession sermons before the university; and they were both printed. The first was entitled "The Principles of the Revolution vindicated." Although it was written with great caution, a report was circulated in London that it was treasonable; but when Mr. Dunning (afterwards lord Ashburton) was asked what he thought of it, he replied, "that it contained such treason as ought to be preached once a month at St. James's." However, it gave great offence to the court, and, in Dr. Watson's opinion, continued to be an obstacle to his preferment. The author was much abused, in consequence of the publication of this sermon, by ministerial writers, as a man of republican principles; but by Mr. Fox, and others of his class, it was very highly commended.

In the same year, 1776, Dr. Watson published his "Apology for Christianity," in reply to Mr. Gibbon's obnoxious chapters in his "History of the Decline and Fall of the Roman Empire." His treatment of the historian was liberal and conciliatory, and was acknowledged with great courtesy and respect. In February 1780, Dr. Watson preached, at the request of the vice-chancellor, the fast sermon before the university, which became very popular, and was widely circulated. In May of this year he published a charge to the clergy of the archdeanery of Ely, at his first visitation; the primary object of which charge was to recommend an establishment at Cambridge, for the express purpose of translating and publishing Oriental MSS., wherever found. Dr. Keene, bishop of Ely, expressed his approbation of this charge; but as he reflected on the

author's politics, he retorts it by observing in a letter to his lordship, "My politics may hurt my interest, but they will not hurt my honour. They are the politics of Locke, Somers, and Hooker; and in the reign of George II., they were the politics of this university." In February 1781, our author was presented by the duke of Rutland with the rectory of Knaploft, in Leicestershire; and as he was just then printing the first two volumes of Chemical Essays, he availed himself of this opportunity of dedicating them to his grace. In 1782, Soame Jenyns published his Disquisitions on various subjects, the seventh of which advanced principles very opposite to those which were contained in the "Principles of the Revolution vindicated," with occasional glances at that sermon. Although our author was scarcely recovered from a dangerous illness, he drew up, in the course of a few hours, "An Answer to the Disquisitions, &c." Upon a change of ministry, lord Shelburne was induced to confer the bishopric of Landaff on Dr. Watson; and on the 26th of July 1782, he kissed hands on his promotion. But he was not very much gratified by this advancement; because lord Shelburne had expressed to the duke of Grafton his expectation that he would occasionally write a pamphlet for their administration. The duke, however, did the new prelate the justice to assure his lordship, that he had totally mistaken the character of the bishop; for though he might write as an abstract question, concerning government, or the principles of legislation, it would not be with a view of assisting any administration. "I had written," says the independent and high-spirited bishop, "in support of the principles of the revolution, because I thought those principles useful to the state, and I saw them vilified and neglected. I had taken part in their petitions against the influence of the crown, because I thought that influence would destroy the constitution, and I saw that it was increasing. I had opposed the supporters of the American war, because I thought that war not only to be inexpedient, but unjust. But all this was done from my own sense of things, and without the least view of pleasing any party: I did, however, happen to please a party, and they made me a bishop. I have hitherto followed, and shall continue to follow, my own judgment in all public transactions: all parties now understand this, and it is probable that I may continue to be bishop of Landaff as long as I live. Be it so. Wealth and power are but secondary objects of pursuit to a thinking man, especially to a thinking Christian." Lord Shelburne seems to have courted an intimate acquaintance with the bishop; alleging that he had Dunning to assist him in law points, and Barry in army concerns, and expressing his wish to consult him in church matters. The bishop availed himself of this overture, and proposed to the minister a plan by which service might be done to religion and to the established church. Being invited to dine with his lordship, he put into his hand a paper, containing the following scheme of reform, comprehending the doctrine, the jurisdiction, and the revenue of the church of England. The two following hints on the subject of the revenue he submitted to the consideration of his lordship:—"First, a bill to render the bishoprics more equal to each other, both with respect to income and patronage; by annexing, as the richer bishoprics became vacant, a part of their revenues, and a part of their patronage, to the poorer. By a bill of this kind, the bishops would be freed from the necessity of holding ecclesiastical preferments *in commendam*; a practice which bears hard on the rights of the inferior clergy. Another probable consequence of such a bill would be, a longer residence of the bishops in their several dioceses; from which the best consequences

sequences both to religion, the morality of the people, and to the true credit of the church, might be expected: for the two great inducements to wish for translations, and consequently to reside in London, namely, superiority of income, and excellency of patronage, would in a great measure be removed. Second, a bill for appropriating, as they become vacant, one half, or a third part, of the income of every deanery, prebend, or curacy, of the churches of Westminster, Windsor, Canterbury, Christchurch, Worcester, Durham, Ely, Norwich, &c. to the same purposes, *mutatis mutandis*, as the first fruits and tenths were appropriated by queen Anne. By a bill of this kind, a decent provision would be made for the inferior clergy, in a third or fourth part of the time which queen Anne's bounty alone will require to effect it. A decent provision being once made for every officiating minister in the church, *the residence of the clergy in their cures might more reasonably be required than it can be at present, and the licence of holding more livings than one be restricted.*" Lord Shelburne wished to be informed if nothing could be gotten from the church to relieve the burdens of the state; to which the bishop replied, that the whole revenue of the church would not yield, if it were equally divided, which could not be thought of, above 150*l.* a year to each clergyman, which could not be thought too ample; and in a political view it would be highly inexpedient, unless government would be contented to have a beggarly and illiterate clergy, which no wise minister would ever wish to see. In prosecution of the same plan, the bishop sent a letter to the archbishop of Canterbury, and a copy to lord Shelburne, the duke of Grafton, the duke of Rutland, and lord John Cavendish respectively. The minister discouraged the business, and earnestly dissuaded the bishop from any immediate publication of it. Upon the resignation of lord Shelburne, who, by an exercise of prerogative, had been nominated by the king without the recommendation of the cabinet, the coalition ministry, formed of lord North, and others who had for many years reprobated his political principles, came into power. This circumstance of the coalition roused our prelate's indignation, and led him to entertain a very unfavourable opinion of the disinterestedness and integrity of those to whom he had been invariably attached. Although the badness of the peace, and the supposed danger of trusting power in the hands of lord Shelburne, were the ostensible reasons for this coalition, personal dislike of him, and a desire to be in power themselves, were, in the bishop's judgment, the real ones. This dissension of the Whigs, he says, did more injury to the constitution than all the violent attacks on the liberty of the subject, which were subsequently made during Mr. Pitt's administration. "This apostacy from principle in the coalition ministry ruined," as he conceived, "the confidence of the country, and left it without hope of soon seeing another respectable opposition on constitutional grounds; but it stamped on the hearts of millions an impression which will never be effaced, that *patriotism is a scandalous game played by public men for private ends, and frequently little better than a selfish struggle for power.*"—"It is," he adds, "a principle with all parties to require from their adherents an implicit approbation of all their measures: my spirit was ever too high to submit to such a disgraceful load of political connection."—"To forget all benefices, and to conceal the remembrance of all injuries, are maxims by which political men lose their honour, but make their fortunes."

Our prelate's letter to the archbishop of Canterbury was published in the interval between lord Shelburne's resignation and the appointment of the duke of Portland to the head of the treasury; but though a copy of it was sent to

each bishop, none thought proper to acknowledge it except Dr. Porteus, then bishop of Chester. Soon after the failure of Mr. Fox's East India bill, to which Dr. Watson was adverse, Mr. Pitt was appointed first lord of the treasury; and though he had continued in office for several weeks previously to the dissolution of parliament, March 25th, 1784, in direct opposition to the majority of the house of commons, which in the judgment of our prelate established a dangerous precedent, yet deference to the sense of the nation declared by numberless addresses to the king against the coalition ministry, induced him to acquiesce. In July of this year he wrote a letter to Mr. Pitt, recommending an union of Britain and Ireland on an equal and liberal footing; but it was not accomplished till sixteen years after this period, and not, as the bishop observes, "in the liberal way it ought to have been done." Enlarged and liberal as were his sentiments of toleration, he nevertheless regarded the church of Rome as a persecuting church; and he thought it was more necessary to guard against the danger to be apprehended by Protestants in a country where popery is simply tolerated than where it is the established religion. On another occasion he expresses sentiments which must lead the friends of Catholic emancipation to conclude, that he was not favourable to this object. "The persecuting spirit of the Roman church remains in the hearts of the generality of its members," he says, "and whilst it does remain, popery must be watched, intimidated, and restrained." In a letter to Mr. Wakefield written in 1784, he avows his belief of the pre-existence of Christ as the doctrine of the New Testament; but at the same time he is far from concurring with those who brand the supporters of it as enemies to the Christian system. In the same year he addressed a letter to Mr. Wyvill, expressing his warmest wishes for parliamentary reform, which Mr. Pitt seemed at the commencement of his administration inclined to promote. In 1785 he published his "Collection of Theological Tracts," in six volumes, intended for the benefit of young persons, who could not afford to purchase many books in divinity; the design was laudable, and was generally approved; though, he says, the bishops were not pleased with his having printed some tracts originally written by Dissenters. In January 1786 he lost his friend Mr. Luther, with whom he had lived on terms of the most affectionate intercourse for thirty years; and in mentioning this circumstance he gratefully acknowledges his generous bequest, which enabled him to preserve his independence, and to provide for his family. To his Sussex estate, from the sale of which he derived 20,500*l.*, this generous testator added the entail of his estate in Essex. Having, in the year 1782, published a third volume of his Chemical Essays, he presented to the public a fourth volume in 1786. About this time application was made to him by government for advice relating to the improvement of gun-powder; and he suggested a plan of making charcoal by distilling the wood in close vessels, which was carried into execution at Hythe in 1787, and which produced a considerable saving in the manufacture of this article.

Dr. Watson, having been attacked with a disorder in 1781, which continued and rendered the discharge of his duty, as professor of divinity, very irksome to his feelings, and likely to hasten the termination of his life, intimated to Mr. Pitt his wishes for some kind of preferment that would enable him to resign his professorship; his church income, exclusive of it, being only about 1200*l.* a year. This application he very reluctantly renewed, but it produced no effect; and the consequence was a kind of remonstrance, in the tone of complaint, on the part of the bishop to the minister.

nister. About this time Mr. Pitt consulted the bishops about the repeal of the Test and Corporation Acts; and of all the bishops who were assembled for the discussion of the subject bishop Watson and bishop Shipley were the only two who voted, that they ought not to be maintained. The question was afterwards lost in the commons by a majority of 78; 178 to 100. When it was brought forward again in 1789, it was lost by a majority of 20; 122 to 102. But in 1790, the majority against it was 194; 299 to 105: the clamour of "the church is in danger" having in the mean while been widely and loudly circulated, under the sanction of some imprudent or misunderstood expressions in the publications of Dr. Hartley and Dr. Priestley. The bishop's interest with the minister was not promoted by the part which he took on this occasion, and much less by his parliamentary speech against Mr. Pitt's commercial treaty with France. Soon after this he was very much enfeebled by a dysentery; and upon his return from Bath to Cambridge in 1787, the senate appointed Dr. Kipling to be his deputy as professor, with a salary amounting in a course of time to two-thirds of the value of the professorship, when Dr. Watson first undertook it. At the ensuing commencement he delivered a kind of farewell address to the university, in which he expressed his warmest wishes for its prosperity; after having been incessantly engaged in its business for more than thirty-three years. After the commencement he took a journey to Westmoreland, with a view to the re-establishment of his health. He now determined to become an agriculturist; and his pursuits in this department, as an improver of land and planter of trees, were so favourable to his health, and upon the whole so profitable, that he says in the year 1809, "I feel much satisfaction at this moment in having, by my own exertions, wholly counteracted the effects which might otherwise have followed the neglect I have experienced from the court or from its ministers, or from both, that I sincerely pity, and cordially forgive the littleness of mind, which, in some one or other, has occasioned it." The bishop relates an incident which occurred on occasion of his attending a levee in November 1787, and which sufficiently evinced the pains that had been taken to instil wrong notions of his political principles into his majesty's mind. "I was standing," he says, "next to a Venetian nobleman; the king was conversing with him about the republic of Venice, and hastily turning to me said, 'there now, you hear what he says of a republic.' My answer was, 'Sir, I look upon a republic to be one of the worst forms of government.' The king gave me, as he thought, another blow about a republic. I answered that I could not live under a republic. His majesty still pursued the subject: I thought myself insulted and firmly said, 'Sir, I look upon the tyranny of any one man to be an intolerable evil, and upon the tyranny of a hundred to be a hundred times as bad;' thus ended the conversation."

Although Dr. Watson, as professor of divinity, had been for many years a chartered member of the society for propagating the gospel in foreign parts, he had never subscribed to it nor attended its meetings; because its missionaries were more busily employed in bringing over Dissenters to episcopacy than in converting heathens to Christianity.

In the year 1788 he published a charge which he had delivered at his visitation, entitled "An Address to Young Persons after Confirmation." Towards the close of this year and the commencement of the next, he took an active part in the business of the regency, occasioned by the king's mental derangement; and in an elaborate speech delivered in the house of lords January 22d, 1789, he discussed, with singular ability, the subject in debate between Mr. Fox, who asserted "that

the prince of Wales had a right to assume the regency," and Mr. Pitt, who had said, "that the prince of Wales had no more right to assume the regency than any other man in the kingdom had." The part he took on this occasion is said to have offended the queen; who, as he says, "distinguished by different degrees of courtesy on the one hand, and by meditated affronts on the other, those who had voted with, and those who had voted against the minister." At the drawing-room, held on the king's recovery, the bishop was received with a degree of coldness, "which would have appeared to herself ridiculous and ill-placed could she have imagined how little such a mind as mine regarded, in its honourable proceedings, the displeasure of a woman, though that woman happened to be a queen." The prince of Wales, who was witness to this conduct, paid particular attention to the bishop, invited him to dine at Carlton-house, and entered into a familiar conference with him; the bishop on the occasion "advising him to persevere in dutifully bearing with his mother's ill-humour, till time and her own good sense should disentangle her from the web which ministerial cunning had thrown around her." When the bishop, before the close of the interview, declared that he was sick of parties, and should retire from all public concerns, "No," said the prince, "and mind who it is that tells you so, you shall never retire; a man of your talents shall never be lost to the public." The bishop's reflection subjoined to this anecdote is, "I have now lived many years in retirement, and, in my 75th year, I feel no wish to live otherwise." About ten years after the publication of the tract which he had given to the young persons of his diocese, already mentioned, Mr. Ashdown of Canterbury addressed two letters to him, in which he contended that the distinction of ordinary and extraordinary operations of the Holy Spirit is not founded in scripture, and that if it were, both operations ceased with the apostolic age. In reference to this opinion, the bishop declares, "I am not ashamed to own, that I give a greater degree of assent to the doctrine of the extraordinary operation of the spirit in the age of the apostles, than I do to that of his immediate influence, either by illumination or sanctification, in succeeding ages. Notwithstanding this confession, I am not prepared to say, that the latter is an unscriptural doctrine: future investigation may clear up this point, and God, I trust, will pardon me an indecision of judgment proceeding from an inability of comprehension. If it shall ever be shewn, that the doctrine of the ordinary operation of the Holy Ghost is not a scripture doctrine, Methodism, Quakerism, and every degree of enthusiasm, will be radically extinguished in the Christian church; men, no longer believing that God does that by more means which may be done by fewer, will wholly rely for religious instruction, consequent conversion, and subsequent salvation, on his Word."

In the summer of 1789, our bishop, in pursuit of his plan for retiring from public life, laid the foundation of his house on the banks of the Winandermere; where he continued till his death. On occasion of the publication of "Hints to the New Association, recommending a Revival of the Liturgy, &c." in 1789, by the duke of Grafton, two pamphlets were in the following year published in opposition to these "Hints." The bishop made a reply to these attacks; and took a comprehensive view of the subject. Although he was dissuaded from publishing his tract, it soon appeared under the title of "Considerations on the Expediency of revising the Liturgy and Articles of the Church of England," by a Consistent Protestant. Moreover, it was proposed, in conversation with the duke of Grafton, to commence a reform, by the introduction of a bill into the

house of lords, for expunging the Athanasian creed from the Liturgy; but on account of the French revolution, the design was postponed. In this connection, we cannot forbear mentioning what is called the Windsor anecdote. It is as follows; and given by the bishop on the authority of Dr. Heberden: "The clergyman there, on a day when the Athanasian creed was to be read, began with *Whosoever will be saved*, &c. the king, who usually responded with a loud voice, was silent; the minister repeated, in a higher tone, his *Whosoever*; the king continued silent; at length the Apostle's creed was repeated by the minister, and the king followed him throughout with a distinct and audible voice." "I certainly dislike," says the bishop, "the imposition of all creeds formed by human authority; though I do not dislike them, as useful summaries of what *their compilers believe* to be true, either in natural or revealed religion." In a letter to the duke of Grafton, dated October, 1791, he briefly states his sentiments on several subjects of importance. Amongst other observations that deserve attention, he says, "In England we want not a fundamental revolution; but we certainly want a reform both in the civil and ecclesiastical part of our constitution; men's minds, however, I think, are not yet generally prepared for admitting its necessity. A reformer of Luther's temper and talents would, in five years, persuade the people to compel the parliament to abolish tithes, to extinguish pluralities, to enforce residence, to confine episcopacy to the overseeing of dioceses, to expunge the Athanasian creed from our liturgy, to free Dissenters from test acts, and the ministers of the establishment from subscription to human articles of faith. These, and other matters respecting the church, ought to be done: I want not courage to attempt doing what I think ought to be done; and I am not held back by considerations of personal interest; but my temper is peaceable, I dislike contention, and trust that the still voice of reason will at length be heard.—As to the civil state, it cannot long continue as it is, &c. &c." In a charge delivered in 1792, the bishop touched on several subjects of importance and general interest; and among other things on the injustice and impolicy of our Test and Corporation Acts. "There seem to me," says our prelate, "but two reasons for excluding any honest man from eligibility to public office;—want of capacity to serve the office, and want of attachment to the civil constitution of the country. That the Dissenters want capacity will not be asserted; that they want attachment to the civil constitution of the country is asserted by many, but proved by none."—"The Dissenters are neither Tories nor Republicans, but friends to the principles of the revolution;" but their conduct since the revolution, and at and since the restoration, proves that they have no design to undermine the constitution of the country.

"But it may be said, that inasmuch as the Dissenters are enemies to the church establishment, and that the state is so allied to the church, that he who is unfriendly to the one must wish the subversion of both. I think this reasoning is not just; a man may certainly wish for a change in an ecclesiastical establishment, without wishing for a change in the civil constitution of a country. An Episcopalian, *e. g.* may wish to see bishops established in all Scotland, without wishing Scotland to become a republic: and he may wish that episcopacy may be established in all the American states, without wishing that monarchy may be established in any of them. The protection of life, liberty, and property, is not inseparably or exclusively connected with any particular form of church-government. The blessings of civil society depend upon the proper execution of good laws, and upon the good morals

of the people; but no one will attempt to prove, that the laws and morals of the people may not be as good in Germany, Switzerland, Scotland, under a Presbyterian, as in England or France, under an episcopal form of church-government," with much more to the same purpose.

In the year 1795 our bishop made a speech in the house of lords in favour of a motion by the duke of Bedford, "that no form of government which may prevail in France should preclude a negotiation with that country, or prevent a peace whenever it could be made consistently with the honour, interest, and security of the nation." In the following summer he published a charge, and two sermons, one of them entitled "Atheism and Infidelity refuted from Reason and Scripture;" and the other "The Christian Religion no Imposture." In 1796 he published "An Apology for the Bible," in defence of it against the scurrilous abuse of Thomas Paine. Of this tract many thousands were distributed at a low price, both in England and Scotland; and we have reason to believe produced the most beneficial effects, not only in Great Britain, but in Ireland and America. In 1798 the bishop published an address to the people of Great Britain, which was of great service in raising the spirit of the nation. In 1799 he delivered a speech, recommending and vindicating against objections a cordial union with Ireland, as an event which would enrich Ireland without impoverishing Great Britain: and that would render the empire, as to defence, the strongest in Europe. When Mr. B. Flower was brought to the bar of the house of lords for a breach of privilege in publishing something against the above-mentioned speech, the bishop, when he heard of it, declared, "that he should feel much more satisfaction in forgiving the man's malignity than in avenging it."

In 1805 the petition of the Roman Catholics of Ireland was taken into consideration by both houses of parliament, and rejected by great majorities in both. Previously to the discussion on this question, bishop Watson communicated his sentiments on the subject in a letter addressed to the duke of Grafton. As this is a question still *sub judice*, we shall here introduce the general heads of argument suggested in relation to it by the bishop. "1. The absolute justice of tolerating religious opinions, since no civil government can justly possess more power over its subjects than what individuals have consented to transfer to it when they entered into society; and no individual can give up the right of worshipping God according to his conscience, and therefore no government can justly abridge that right. 2. No civil government has any right to take cognizance of opinions either political or religious, but merely of men's actions. This principle, however, is liable to exception with respect to the public teachers of religion. 3. The established religion of every country ought to be the religion of the majority of the people; unless an exception be admitted, when the minority of the inhabitants possess a majority of the property by which the establishment is maintained; and even in that case, humanity and policy, if not strict justice, require a co-establishment of the religion of the minority. 4. Great credit ought to be given to men of probity and talents, disclaiming, in express terms, the most obnoxious principles of the church of Rome; the odium of past transactions ought not to be thrown upon those who had no concern in them. 5. Constitutionally speaking, the Catholic peers and commons have no more right to sit in parliament than a Catholic king has to sit upon the throne; and if the change of times is not yet such that a Protestant would endure the thought of a Catholic king upon the throne, it may be inquired upon what principle it is that a Protestant can endure

endure the thought of a Catholic legislator. The principle may be the little comparative influence of a Catholic legislator, and his abjuration of temporal tenets formerly professed by Catholics. 6. The progress of science has subdued the bigotry formerly too apparent not only in the church of Rome, but in all the reformed churches: and it will never be able, till a state of ignorance and barbarism recurs, to rear up its head again. There is no probability of intolerance and superstition ever more pervading Europe; and the Catholic religion will continue to derive light from the labour of learning. The learned Catholics are beginning every where to soften the asperities of their religious tenets, and to apologize for what they cannot excuse. The Irish gentry partake of the illumination of the age; and the peasantry will imitate the example of their superiors. 7. It may be said that the church of Rome has not formally renounced any of the doctrines maintained at the council of Trent, and that the court of Rome has not abandoned any of its pretensions to temporal dominion; yet Catholic, as well as Protestant, states have every where spurned these pretensions; and something very like a formal renunciation of one of the most dangerous tenets of that church took place in Russia more than twenty years ago. The empress Catharine gave permission to the Roman Catholics in her dominions merely to exercise their religion; and to have bishops of their own persuasion for the government of their church. She was present at the consecration of the first Catholic archbishop. When the ceremony had proceeded to the administration of the oath usually taken by the bishops of that church, the archbishop (that was to be) refused to repeat the clause "Hæreticos schismaticos et rebelles domino nostro papæ pro posse persequar et impugnato." On this refusal, the ceremony was ended, fresh instructions were required from Rome, and the then pope ordered the clause to be omitted; and it has been since omitted, by the authority of the pope, in the oath taken by the Irish bishops."

"My great objection," says Watson, "to the church of Rome is the uncharitable principle of the infallibility of persons out of its pale; for this principle produces a persecuting principle, and I must ever detest every species of persecution. I cannot however believe that Catholic emancipation will tend to the increase of the number of Catholics, either in Ireland or in England; on the contrary, I think the number would, by such a measure, be lessened. Nothing unites men so much as any degree of persecution. Individuals, otherwise of no consequence, either from talents or fortune, become conspicuous, and acquire a degree of weight, when connected with a party. Men claim merit from what they call their sufferings, who would have no ground for claiming it on any other species of desert."

In subsequent letters addressed to lord Grenville in 1810, and to sir John Cox Hippesley in 1812, he gives the following opinion of the *veto*: "the appointment of the Irish Catholic bishops ought to be in the king, if they are to be paid by the state; and if they are to be paid by the Catholics themselves, it ought to be in them; but exclusive of all foreign influence, recommendation, or confirmation. If they do not accede to this, or to something similar to this, they will act on a principle which I did not expect, nor can approve." In a letter to lord Hardwicke, dated April 2, 1812, he says, "I make no secret of my opinion; a cordial reception of Catholics and Dissenters into the bosom of the constitution, by the extinction of all disqualifications, is become necessary to secure the independence of the empire, and the safety of the country."

In consequence of an imputation of want of orthodoxy, partly occasioned by a sermon published by the bishop, and

entitled "A Second Defence of revealed Religion," he makes the following reflections on the ground of this charge. "What is this thing called orthodoxy, which mars the fortunes of honest men, misleads the judgment of princes, and occasionally endangers the stability of thrones? In the true meaning of the term, it is a sacred thing, to which every denomination of Christians lays an arrogant and exclusive claim, but to which no man, no assembly of men, since the apostolic age, can prove a title. It is frequently, among individuals of the same sect, nothing better than self-sufficiency of opinion, and pharisaical pride, by which each man esteems himself more righteous than his neighbours. It may, perhaps, be useful in cementing what is called the alliance between the church and state; but if such an alliance obstructs candid discussions, if it invades the right of private judgment, if it generates bigotry in churchmen, or intolerance in statesmen, it not only becomes inconsistent with the general principles of Protestantism, but it impedes the progress of the kingdom of Christ, which we all know is not of this world."

The next public occasion on which our bishop distinguished himself was on the debate which took place in the house of lords, March 23, 1807, concerning the abolition of the slave-trade. For the affirmative of this question he delivered a speech, abounding with historical information and found argument. When the administration that had been formed on the death of Mr. Pitt was dismissed, he expressed in strong terms his disapprobation of the ostensible reason alleged for its dismissal, which was the king's dislike of a measure which had been brought forward in parliament respecting the Irish Catholic officers; and the requisition on the part of his majesty of a pledge that this administration would never more bring forward the question of granting farther indulgence to the Irish Catholics. This requisition was considered by many as having a tendency dangerous to the constitution; and to Dr. W. it appeared "to be not in words, but in fact, a declaration of a *sic volo*." On occasion of the dismissal of this "half Whig, and half Tory administration," as he calls it, he communicated to lord Grenville a resolution, which he conceived to be fit to be introduced in the house of lords, whenever the subject should be brought forward, and which lord Grenville actually adopted *in toto*, as better in his opinion than any thing which had occurred either to himself or to his friends. The resolution was as follows: "Resolved, that whoever has advised, or shall in future advise, his majesty to require from his confidential servants a pledge, that they will, on any occasion, abstain from submitting to his consideration any measure of government which they, in their consciences, believe to be conducive to the public weal, is and ought by this house to be declared to be an enemy to the constitution of this country." Soon afterwards he sent to the duke of Grafton a less firm resolution, which he thought might be more acceptable to the then house of lords. Neither of these resolutions, however, was ultimately adopted; but the resolution that was actually proposed was, after a debate which lasted till 7 o'clock in the morning, negatived by a great majority. A violent alarm against Popery and of the church's danger prevailed, during which the bishop declared his opinion, "that it was both just, and in the state of Buonaparte's strength and temper towards us, highly expedient, to receive both Catholics and Dissenters into the bosom of the constitution; but that it was improper to press any innovation till the people were prepared to receive it; and that" (in his opinion) "the time was not yet come for the general adoption of such a political and equitable principle of government. Toleration was in every man's mouth; but do-

minion over the faith of other men, exclusion from privileges possessed by themselves, and a disposition to the exercise of *power without right*, were in the hearts of a great part, probably of a majority of the people of Great Britain."

In reply to a letter, in which the writer expresses a wish, that the bishop would answer Mr. Malthus's book, intitled "An Essay on Population," and in which, as he represents it, the author endeavours to establish a code of morality in opposition to the morality of the gospel, Dr. W. observes that Mr. Malthus appeared to him to be "endeavouring to shew the utility of bringing down the population of the earth to the level of the subsistence requisite for the support of man," (a proposition wanting no proof, since where there is no food, man must die,) "and that in his judgment, his time and talents would have been better employed in the investigation of the means of increasing the subsistence to the level of the population." He says, however, that after having looked into this book, he was justified in neglecting to peruse it, as it thwarted the strongest propensity of human nature, and contradicted the most express command of God, "Increase and multiply;" more especially as he was persuaded, "that the earth had not, in the course of 6000 years from the creation, ever been replenished with any thing like one half the number of inhabitants it would sustain."

The bishop might indeed well regret, as he frequently, perhaps *too frequently* does, the inattention to his merits, and claims on higher preferment than a poor Welsh bishopric, which he had long experienced, after a long course of literary labour and public service. Mr. Pitt professed himself well disposed towards him, but alleged "that a *certain person* would not hear of it." "Notwithstanding this anecdote," says the bishop, "I cannot bring myself to believe that the king was either the first projector, or the principal actor in the sorry farce of neglecting a man whom they could not dishonour, of distressing a man whom they could not despise, which has been playing at court for near 26 years." Acquitting Mr. Pitt, though he knew that no minister would be very zealous in promoting a man who professed and practised parliamentary and personal independence, from the charge of forgetting either obligations or connections in the pursuit of his ambition, he lays the blame on a more exalted personage. "As to the king's dislike of me, unless his education had made him more of a Whig, it was natural enough. My declared opposition to the increased and increasing influence of the crown had made a great impression on his majesty's mind."

Of the bill, introduced into the house of commons by the chancellor of the exchequer in 1808, for making more effectual provision for the maintenance of stipendiary curates in England and Wales, and for their residence on their cures, he expressed his disapprobation, with the reason of it, in letters addressed both to the archbishop of Canterbury and Mr. Percival. He rejoiced, however, in the grant of 100,000*l.* a year by a vote of parliament in 1809, in lieu of queen Anne's bounty; but in his charge of that year, referring to a letter previously written to lord Hawkebury on this occasion, he renews his complaint of the manner in which he had been neglected, alleging that he never had any place of residence amongst his clergy, nor a church-income sufficient to enable him to attend every year his parliamentary duty. Having, in the year 1809, and during an extensive visitation of his diocese, held a confirmation at Merthyr-Tydvil, he was hospitably accommodated at the house of the late Mr. Crawshay, a well-known iron-master, whose hospitality the writer of this article has experienced;

and before he left the diocese, Mr. C. came to Landaff to take leave of him. On this occasion, taking the bishop by the hand, he said to him, "If ever you have occasion for 5 or 10,000*l.* it shall be wholly at your service." Of course declining to avail himself of this generous offer, he nevertheless declares, "I was more delighted with this substantial proof of the disinterested approbation of an iron-master than I should have been with the possession of an archbishopric acquired by a selfish subserviency to the despotic principles of a court."

On the subject of Lancasterian schools and bible societies, he declares his opinion to be, "that certain zealous men in the established church have suffered their apprehensions for its safety to outstrip all probability of danger arising to it, from the institution of either Lancasterian schools or auxiliary bible societies. The church is in no danger from Protestant or Catholic Dissenters; but the state must ever be in danger from discontent breeding disaffection, whilst a large portion of its members is looked upon by government with a jealous and repulsive eye." On another occasion, in a letter to Mr. Wyvill, Oct. 21, 1813, he expresses sentiments of a similar kind: "the struggle for the liberty of Europe has been most nobly sustained by Great Britain, and might it not at this period be successfully terminated by our government granting emancipation to the Catholics, and a repeal of the Test and Corporation acts to the Dissenters? These concessions would be more powerful means of defence than all the confiscations of our enemy can ever be to the contrary." We cannot forbear subjoining a paragraph from Mr. Wyvill's reply: "Mr. Fox proved the sincerity of his attachment to liberty, civil and religious, by the long service of 30 years, almost wholly spent in parliament, under the frowns of power: your lordship, I believe, has given a similar proof of your attachment to that best of causes. You have endured a similar proscription from men who acted on the same unworthy motives, and the consequence has been almost the same: you have at Landaff been so long shut out from the road to the higher honours of the church. But how much higher have you risen by having obtained the undisputed dignity of virtue, benevolence, patriotism, and the true spirit of Christianity!" Well might the bishop reply to Mr. Wyvill, "I am proud of *your* honourable testimony to that political consistency of principle, which unites my name to that of Mr. Fox."

From this period the health of the bishop rapidly declined; and though his mental faculties continued unimpaired, yet bodily exercise and literary composition became irksome to him. He expired on the 4th of July, 1816, in the 79th year of his age; illustrating, as the publisher of his Memoirs says, in death the truth of his favourite rule of conduct through life: "Keep innocency, and take heed unto the thing that is right, for that shall bring a man peace at the last."

Having availed ourselves of the work now before us, we make no apology for extending this article beyond the usual limits of our biographical sketches. From the honour of an early acquaintance with the subject of this article, and from a full conviction of his uniform integrity, as well as his pre-eminent talents, we felt a peculiar interest in the perusal of the memoirs of his life. Distinguished by mental powers of a superior order, and by public services which have seldom been paralleled, we pay this tribute of respect to his memory. His character needs no delineation besides the "Anecdotes" which his own pen has furnished. In every department which he occupied, first as a student, and afterwards as a tutor and professor in the university of Cambridge, as a prelate and a member of the legislature, and in

the latter period of his life as an agriculturist, his assiduity and activity were indefatigable and persevering. To say nothing of his solicitude for the best interests of his friends and his family, the ardour of his zeal in promoting the honour and prosperity of the church and civil community to which he belonged, by those means which, according to his comprehensive and liberal views, he thought to be most conducive to this purpose, must approve itself in a high degree to those who entertained sentiments similar to his own, and it will need little apology in the candid judgment of those who most differ from him in their opinion of public men and public measures. As he always spoke and acted from the conviction of a well-informed and upright mind, and counteracted his own secular interest by the course he pursued, his sentiments claim deference, and his conduct will command respect. If it should occur to any who peruse the anecdotes now before us, that he was too ambitious of preferment, it must be recollected, that the merit of his services, both to the church and state, of which he could not be unconscious, and the elevated connections which his station in the university had led him to form, encouraged reasonable expectations of a higher rank in the church than a poor bishopric in Wales; so that he could not otherwise than feel himself neglected and disappointed. His private fortune, though his patrimony had been expended, was rendered ample by the liberality of his friend Mr. Luther, and therefore he had no just reason for complaint on this account; and yet it should be considered that he had a family, for which he wished to provide in a manner suitable to the circumstances in which his aggregate income had placed them. Anecdotes of the Life of Richard Watson, bishop of Landaff, written by himself at different intervals, and revised in 1814, &c., published by his son, Richard Watson, LL.B., prebendary of Landaff and Wells. Lond. 1817.

WATSON, in *Geography*, a town of Virginia; 35 miles S.W. of Richmond.

WATSON'S *Island*, an island in the Mergui Archipelago, of an oval form, and about 12 miles in circumference. N. lat. $9^{\circ} 36'$.

WATSONIA, in *Botany*, was so called by Miller, after the late Sir William Watson, knight, M.D. F.R.S., well known by his numerous papers in the Philosophical Transactions, on many subjects connected with the history of Botany, and eminently distinguished for his cultivation of several branches of philosophical and medical knowledge. Miller's genus being sunk by Linnæus in *Antholyza*, the *Büttneria* was called *Watsonia* by Boehmer; but the original one, restored by Mr. Ker, is now generally, and with great propriety, adopted.—Mill. Ic. 184. Ker in Sims and Kon. Ann. of Bot. v. 1. 229. Dryand. in Ait. Hort. Kew. v. 1. 93.—Class and order, *Triandria Monogynia*. Nat. Ord. *Enfata*, Linn. *Irides*, Juss.

Gen. Ch. *Cal.* Spatha inferior, shorter than the corolla, of two oblong, close-pressed, permanent valves. *Cor.* of one petal, superior: tube cylindrical throughout, somewhat enlarged, but not spreading, in the elongated throat, curved: limb nearly regular, in six deep, flat, spreading, almost equal segments. *Stam.* Filaments three, inserted into the tube at the origin of the throat, thread-shaped, ascending, shorter than the corolla; anthers oblong, somewhat parallel, incumbent. *Pist.* Germen inferior, oblong, furrowed; style thread-shaped, longer than the stamens; stigmas three, slender, deeply cloven, spreading, recurved. *Peric.* Capsule oblong, bluntly triangular, cartilaginous, of three cells and three valves. *Seeds* numerous, imbricated downwards, angular in their lower part, dilated into more or less of a wing at the upper end.

Ell. Ch. Spatha of two valves. Corolla tubular, with a cylindrical throat; its limb in six deep, nearly equal, segments. Stigmas three, thread-shaped, deeply cloven, the segments recurved. Capsule cartilaginous. Seeds numerous, angular.

This genus differs from *GLADIOLUS* in its almost regular corolla, with a cylindrical throat; narrow, divided, not dilated, stigmas; and angular, scarcely winged, seeds: *ANTHOLYZA*, as now limited, is distinguished from it, by having a ringent limb, of unequal and dissimilar segments; simple stigmas; and nearly globular seeds. See those articles.

1. *W. spicata*. Hollow-leaved *Watsonia*. Ker in Curt. Mag. at p. 553. Ait. n. 1. (*Ixia spicata*; Willd. Sp. Pl. v. 1. 200. I. *cepacea*; Redout. Liliac. t. 96. I. *fistulosa*; Curt. Mag. t. 523. I. *alopecuroides*; Linn. Suppl. 92. *Gladiolus spicatus*; Linn. Sp. Pl. 53. Thunb. Gladiol. n. 13. *G. fistulosus*; Jacq. Hort. Schoenbr. v. 1. 8. t. 16.)—Leaves cylindrical, hollow.—Gathered by Thunberg, on the highest hills of Hottentot's Holland, at the Cape of Good Hope, flowering in December and January. By Sir Joseph Banks's herbarium, this species appears to have been cultivated by Mr. W. Malcolm, in 1791. It blooms in the European green-houses in May, but not very readily, often bearing small oat-like bulbs in the place of flowers. The bulb is small, round, with a fibrous coat. Stem leafy, from eight to twelve inches high. Leaves alternate, very remarkable for their cylindrical inflated form, gradually swelling upwards, obtuse, with a small point; their surface very smooth; their base sheathing. Flowers either light blue or pale purple, very numerous, closely imbricated in a two-ranked tapering spike, with reddish crenate sheaths. Corolla regular, expanding rather more than half an inch. We do not find that the stigmas of this plant are cloven, as the generic character requires, and we should rather have left it in *Ixia*, till it could otherwise have been disposed of. The same remark applies to the following. The name *spicata* is not so exclusively appropriate as *fistulosa* or *cepacea* would have been, but it is the oldest name, and liable to no objection. This is certainly, as far as we can make out, the original *Gladiolus spicatus* of Linnæus, though he, long after its publication, very inadvertently laid into his herbarium, under that name, a Siberian specimen of a small-flowered variety of *G. communis*.

2. *W. plantaginea*. Plantain-spiked *Watsonia*. Ker in Curt. Mag. t. 553. Ait. n. 2. (*Ixia plantaginea*; Willd. Sp. Pl. v. 1. 200. *Gladiolus alopecuroides*; Linn. Sp. Pl. 54. Amoen. Acad. v. 4. 301. Thunb. Gladiol. n. 14.)—Upper leaves linear-sword-shaped, many-ribbed: lowermost hollow, compressed. Flowers imbricated in two rows.—Gathered by Thunberg in several places near the town, at the Cape of Good Hope, often in the highways. This differs essentially from the species just described, in having the usual sword-shaped foliage of its natural order. Their flowers nearly resemble each other. These are in the present species either blue or white, very numerous, forming a dense two-ranked spike, with membranous-edged sheaths, recalling the idea of some kind of Plantain. Sometimes each stem bears two or three such spikes, which are then very large and luxuriant; but in our cultivated specimens they are usually solitary, as well as much smaller. The flowers are without scent.

3. *W. punctata*. Dotted-flowered *Watsonia*. Ker in Ann. of Bot. n. 1. Ait. n. 3. (*Ixia punctata*; Andr. Repof. t. 177.)—Leaves linear-awl-shaped, compressed. Spike about three-flowered.—Sent from the Cape of Good Hope, in 1800, by Mr. Niven, to his employer Geo. Hibern,

bert, esq. in whose green-house at Clapham it flowered the spring following. *Bulb* roundish, depressed. *Stem* leafy, slender, about a foot high. *Leaves* few, alternate, very narrow, spreading in two directions. *Flowers* agreeing in size and disposition with those of *Ixia maculata*, about three in number, of a fine purple, marked with dotted or beaded veins; their segments regular, elliptical, longer than the tube, three of them rather smaller than the rest. *Stigmas* three, deeply divided; or rather, we should say, six, strap-shaped, obtuse, revolute, downy. The character of the *stigmas* answers to *Watsonia*, but the habit is very unlike the other species.

4. *W. marginata*. Broad Bordered-leaved *Watsonia*. Ker in Curt. Mag. t. 608. Ait. n. 4. (*Gladiolus marginatus*; Linn. Suppl. 95. Willd. Sp. Pl. v. 1. 217. Thunb. Gladiol. n. 20.)—Leaves sword-shaped, with thick callous edges. Spike somewhat compound. Mouth of the corolla with six teeth.—Abundant on grassy hills at the Cape of Good Hope, as well as on the Table-mountain, and other elevated ground, flowering from October to December often in such profusion, as to cover the hills as it were with a beautiful rose-coloured carpet. *Thunberg*. In our green-houses it readily blossoms from June to August, especially if planted in deep pots, and as readily increases, being, as Mr. Ker observes, become within a few years one of the commonest of its tribe. The great size of the plant, its thick-edged leaves, not indeed well expressed in the Botanical Magazine, and the copious, rose-coloured flowers, smelling like Hawthorn, or Heliotrope, render this one of the most desirable and striking of the Cape bulbs. The corolla is regular, with a tube about equal to its limb, having a short cylindrical throat. *Stigmas* long, each in two divaricated revolute segments.

5. *W. rosea*. Pyramidal-spiked *Watsonia*. Ker in Ann. of Bot. n. 5. Curt. Mag. t. 1072. Ait. n. 5. (*Gladiolus glumaceus*; Thunb. Prodr. 186. Vahl Enum. v. 2. 105. *G. marginatus* δ ; Thunb. Gladiol. n. 20. *G. iridifolii* varietas; Jacq. Ic. Rar. t. 235. *G. pyramidatus*; Andr. Repof. t. 335.)—Leaves sword-shaped, thickened at the edges. Spike compound. Mouth of the corolla naked.—Native of the Cape of Good Hope. It appears to have flowered, for the first time in England, at the Dowager Lady de Clifford's, in August 1803. One of the largest of its tribe, being sometimes four feet high. We cannot wonder at this having been taken for a variety of the last, at least while the species of this difficult order of plants were but superficially examined. The present is, however, the larger and more stately plant of the two, with even more beautiful rose-coloured flowers, whose corolla wants the six marginal teeth round the mouth, which essentially distinguish the preceding.

6. *W. brevifolia*. Short-leaved *Watsonia*. Ker in Curt. Mag. t. 601. Ait. n. 6. (*Antholyza spicata*; Andr. Repof. t. 56. *Gladiolus testaceus*; Vahl Enum. v. 2. 105.)—Leaves ovate-sword-shaped, equitant, very short. Tube, throat, and limb, of the corolla equal in length; mouth naked.—Native of the Cape of Good Hope, from whence it was imported by Messrs. Lee and Kennedy, through the hands of Mr. Pringle of Madeira, in 1794. The leaves are about four, almost perfectly radical, remarkable for their shortness, being but two or three inches long, though near an inch wide; their edges cartilaginous, though very narrow. *Stem* twelve or eighteen inches high. *Spike* long, erect, simple, or sometimes branched, but not composed of little spikelets. *Flowers* of a tawny red, about the size of *W. marginata*, but the proportion of their tube, and especially their throat, is longer

compared with the limb. Their colour would lead us to expect some fragrance, in the evening at least, but this is said not to be the case. They have, however, the advantage of being much more lasting than some of their allies. The *stigmas* are deeply cloven.

7. *W. iridifolia*. Flag-leaved *Watsonia*. Ker in Ann. of Bot. n. 12. Ait. n. 7. (*Gladiolus iridifolius*; Jacq. Ic. Rar. t. 234. Willd. Sp. Pl. v. 1. 215, excluding the synonym of *G. cardinalis*.)— β . var. *fulgens*; Curt. Mag. t. 600. (*Antholyza fulgens*; Andr. Repof. t. 192. *Gladiolus marginatus* γ ; Thunb. Gladiol. n. 20.)—Throat of the corolla curved, longer than the tube, and rather longer than the acute limb. Leaves sword-shaped, erect, with a prominent midrib.—Native of the Cape of Good Hope, from whence it was sent by Mr. Masson, in 1795. The variety β is preferred, on account of the splendid scarlet colour of its flowers, in which alone it is said to differ from the pale greyish-flowered plant, figured by Jacquin. We have not seen the latter, but if the figure be correct, the tube, and the cylindrical throat, are, each of them, shorter in proportion to the sheath, and to the limb, than in the scarlet kind. The leaves in both are long, erect, and scarcely thickened at the edges, having more of a midrib than the several foregoing species. The spathas, in the scarlet variety, are not much above half the length of the slender tube, which is about two-thirds as long as the greatly-extended, cylindrical, curved, and strongly deflexed throat. The latter exceeds the length of the elliptical, acute, recurved, nearly equal, segments of the limb. Anthers violet. *Stigmas* cloven half way down, divaricated.

8. *W. Meriana*. Red *Watsonia*. Ker in Ann. of Bot. n. 11. Curt. Mag. t. 1194. Ait. n. 8. (*Watsonia*; Mill. Ic. t. 276. *Antholyza Meriana*; Linn. Sp. Pl. 54. Curt. Mag. t. 418. *Gladiolus Merianus*; Willd. Sp. Pl. v. 1. 214. Vahl Enum. v. 1. 94. Jacq. Ic. Rar. t. 230. Redout. Liliac. t. 11. *Meriana flore rubello*; Trew. Ehret. t. 40.)

β . *W. angusta*; Ker Ann. of Bot. n. 9. (*G. Merianæ* var. Jacq. Ic. Rar. t. 231.)—Throat of the corolla curved, rather longer than the tube, and longer than the obtuse limb; tube longer than the spathe. Leaves sword-shaped, erect, with a prominent midrib.—Native of the Cape of Good Hope. Raised from seed, before 1750, in Chelsea garden, by Miller, who first gave it the name of *Watsonia*. A large and handsome species nearly akin to the last, but sufficiently distinct, and characterized by the blunt segments of its corolla. The proper hue of the flowers is a peculiar salmon-coloured red, rather than a scarlet, as may be seen in Miller's and Jacquin's figures, and especially Curtis's t. 418. But the corolla varies in this respect, as well as in size, of which the two extremes are the Botan. Mag. t. 1194, and Jacq. Ic. Rar. t. 231. The latter, which we have never seen in England, was referred to this species by the late Mr. Dryander, from a drawing sent by Jacquin, how justly can only be a matter of opinion, unless living specimens were accurately compared. The species before us flowers with other Cape bulbs in May and June, increasing plentifully by offsets.

9. *W. humilis*. Crimson *Watsonia*. Mill. Ic. t. 297. f. 2. Ker in Curt. Mag. t. 631. 1195. Ait. n. 9. (*Gladiolus laccatus*; Jacq. Ic. Rar. t. 232. Willd. Sp. Pl. v. 1. 215.)—Throat of the corolla curved, rather longer than the acute limb; tube the length of the spathe. Leaves sword-shaped, erect, with a prominent midrib.—Native of the Cape of Good Hope, from whence the seeds were obtained by Miller, in 1754. Much smaller than several of the last described, being seldom above a foot high,

high, with linear *leaves*. The *flowers* are of a crimson, or rose-coloured, hue, not verging towards a scarlet, or tawny red. They vary in size, as may be seen by the two figures in the Botanical Magazine. The *throat* is correctly cylindrical; tube generally shorter than the *spatha*, not longer. We are obliged to content ourselves with the above specific characters, founded on the proportion of these parts, for want of better. Mr. Ker and Mr. Dryander have done much towards the correct discrimination of genera and species in this favourite tribe, but the subject is far from being exhausted.

10. *W. roseo-alba*. Long-tubed *Watsonia*. Ker in Curt. Mag. t. 537. Ait. Epit. 376. (*Gladiolus roseo-albus*; Jacq. Hort. Schoenbr. v. 1. 7. t. 13. Vahl Enum. v. 2. 93.)

β. Variegated with red. Ker in Curt. Mag. t. 1193. Ait. Epit. 376.—Tube about twice the length of the throat, limb, or *spatha*, making nearly a right angle with the throat. Leaves sword-shaped, with a midrib.—Native of the Cape of Good Hope. The *tube* is one and a half or two inches long, erect; throat suddenly deflexed, cylindrical, rather slender, an inch long; segments of the limb lanceolate, acute, the length of the throat. *Anthems* but just projecting out of the mouth of the flower, violet-coloured. *Stigmas* in linear segments. The *corolla* is either cream-coloured, with rose-coloured tints about the mouth and throat, or flesh-coloured blotched with scarlet, or all over crimson. The *flowers* are more numerous and crowded than in *W. Meriana* and its allies. We cannot doubt the distinctness of this species.

11. *W. aletroides*. Aletris-flowered *Watsonia*. Ker in Ann. of Bot. n. 7. Ait. n. 10. Curt. Mag. t. 533. (*Gladiolus tubulofus*; Jacq. Ic. Rar. t. 229. *Antholyza tubulosa*; Andr. Repof. t. 174. *A. Merianella*; Curt. Mag. t. 441, excluding the reference to Miller.)—Throat deflexed, four times as long as the segments of the limb.—Found at the Cape of Good Hope by Mr. Masson, who sent bulbs to Kew garden in 1774. This elegant species bears numerous drooping *flowers*, of a rich crimson, sometimes speckled with a darker tint, or with white, and remarkable for their small slightly-spreading *limb*, so short in proportion to the long tubular deflexed *throat*, that they resemble the flowers of an *Alettris* or *Aloe*. The *leaves* are sword-shaped, narrow, with a central rib not very strongly marked, and several small lateral ones.

12. *W. stridiflora*. Straight-flowered *Watsonia*. Ker in Curt. Mag. t. 1406. Ait. Epit. 376.—Tube thread-shaped, twice the length of the *spatha*; throat erect, very short, slightly dilated; segments of the limb elliptical, obtuse, half the length of the tube. Leaves sword-shaped, with a prominent midrib.—Native of the Cape of Good Hope, from whence it was imported by the honourable W. Herbert. The *stem* is about twelve or eighteen inches high, with several shortish taper-pointed *leaves* at the bottom, and bears about two handsome crimson *flowers*, resembling some of the larger *Ixia*, in the shape, size, and posture of the *limb*, with a very long straight slender *tube*. *Stigmas* divided, as in true *Watsonia*, the only character in which this plant answers to the genus. On the contrary, *Gladiolus Watsonius*, Jacq. Ic. Rar. t. 233. Willd. Sp. Pl. v. 1. 214. Ait. v. 1. 96. Curt. Mag. t. 450 and 569, (see *GLADIOLUS*,) has every character and appearance of a *Watsonia*, even a regular *flower*, except the narrow deeply cloven *stigmas*. We are obliged, therefore, to confess, that these genera do not at present rest on any natural distinction, however different some of their species may be from each other.

WAT-TAUPAUMENE, or ST. PETER, in *Geography*, a river of North America, which runs into the Mississippi, N. lat. 44° 42'. W. long. 93° 38'.

WATTEAU, ANTHONY, in *Biography*, one of the most agreeable painters of the French school, was born at Valenciennes in 1684. His parents were in indigent circumstances, and he was placed with an obscure artist in his native city, to cultivate a talent which manifested itself early. When he was about 16 years old, having already surpassed his preceptor, he connected himself with a scene-painter on his way to Paris, and for some time assisted his associate in decorating the opera-house in that city. When this engagement was completed Watteau found it difficult to rescue himself from the obscurity and embarrassment into which he fell, when happily he became acquainted with Claude Gillot, a painter of grotesque and fabulous subjects, who was pleased with his works and disposition. Gillot afforded him an asylum in his own house, and then instructed him in all he knew of the art, and found an apt and agreeable scholar in his protégée. With the help he thus received from Gillot, and his own admiration and attentive study of the Luxembourg gallery, he formed a taste for colouring, which if not as grand, is at least as agreeable, as ever was employed by any one.

He attempted to prepare himself for historical painting, and studied at the academy with that view; he even was so successful as to obtain the first prize there for an historical picture; but happily he discovered a character of subject quite original and exactly suited to his taste, for which he wisely deserted history, and which has since formed plenty of aspirants, but has never been so successfully practised. The theatre, the opera, fêtes champêtres, masquerades, pantomimes, puppet-shows, afforded him his figures; the gardens of the Luxembourg and of the Thuilleries, of Versailles and St. Cloud, furnished the scenes. In these nature prevails only in the colouring, and that is exquisite, rich, delicate, clear, and full; bright without gaudiness, and deep without blackness; laid on with a freedom, fulness, and delicacy of touch, which no one ever surpassed; but the airs of his figures are generally affected to the highest degree; people of rank and fashion, aping the enjoyments of rural life: and when he attempted to paint domestic or rural scenes, he carried the same taste into his practice. The true character of Watteau's pictures is French gentility, gay, cheerful, debonnaire, of which self-satisfaction is the surest basis. "In his halts and marches of cavalry, the careless strut of his soldiers retains the air of a nation that aspires to be agreeable as well as victorious." Watteau visited England in the reign of George I., but did not enjoy his health here, and returned to France in about a year, where he died in 1721, at the early age of 37.

WATTEN, in *Geography*, a town in Scotland, in the county of Caithness; 7 miles N.W. of Wick.—Also, a town of France, in the department of the North, on the Aa; 4 miles N. of St. Omer.

WATTENSCHIED, a town of Germany, in the county of Mark; 5 miles S.W. of Bockum.

WATTER, a river which rises in the county of Waldeck, and runs into the Erpe, near Volckmarfen.

WATTERPUTTEN, a town of Hindoostan, in Concan; 5 miles S. of Geriah.

WATTINAD, a town of Hindoostan, in the Carnatic; 20 miles S.S.E. of Tanjore.

WATTLE, in *Agriculture and Rural Economy*, a kind of hurdle formed by means of split wood, or small rods, and used for making folds for sheep. The term also signifies a fleshy excrescence growing from under the top of the throats

of animals, such as the cock, turkey, and some others. See HURDLE.

WATTLE-Bird. See *GLAUCOPIS Cinerea*.

WATTLES, in *Rural Economy*, a term applied, in some places, to the rods that are laid upon a roof to be thatched on. This is found an useful and cheap mode for farm buildings in some of the southern districts. See THATCHING.

WATTON, in *Geography*, a small market-town in the hundred of Wayland and county of Norfolk, England, is situated on the confines of what is called the Filand, or open part of the county, at the distance of 21 miles W. by S. from Norwich, and 91 miles N.N.E. from London. Since the making of the turnpike-road through the hundred, Watton has become a place of considerable thoroughfare. It has three annual fairs, and a respectable weekly market on Wednesdays. Great quantities of butter are sent hence for the supply of the London markets. In the enumeration of the population for the year 1811, the parish was stated to contain 177 houses, with a population of 794 persons. The church is very small, being only twenty yards long and eleven broad: the tower is round at the bottom, and octangular at the top. Blomefield was induced, from the appearance of the church, to suppose it was erected so early as the reign of Henry I. It stands at a distance from the town, near the site of the old manorial house; and was evidently so placed to accommodate the tenants of the several hamlets belonging to the manor. On the 25th of April 1673, a dreadful fire happened in the town, when above sixty houses were burnt down, besides outhouses, &c. to the damage of 7450*l.*, and goods to the further value of 2660*l.*: for which a brief was granted to collect throughout England for two years.—Blomefield's *Essay towards a Topographical History of Norfolk*, vol. 2. 8vo. 1805. *Beauties of England and Wales*, vol. xi. Norfolk. By Rev. J. Evans, and J. Britton, F.S.A.

WATTS, ISAAC, D.D. in *Biography*, a Nonconformist divine, eminently distinguished for talents and piety, was born at Southampton in 1674, where, under the tuition of a clergyman of the established church, he made rapid progress in the Latin and Greek languages, and acquired some knowledge even of Hebrew. When it was proposed by some gentlemen who were apprized of his proficiency, to bear the charges of his education in one of the English universities, he declared his purpose of continuing among the Dissenters, though his father, who was of that profession, had often suffered persecution; and at the age of sixteen he was placed under the care of the Rev. Thomas Rowe, who kept an academy in London. Twenty-two Latin dissertations on metaphysical and theological subjects, found among his papers, afford ample evidence of his zealous application during his connection with this institution. Of his poetical talents at the early age of fifteen years several specimens have been preserved, and more particularly a Pindaric ode, addressed to his preceptor Mr. Pinhorn. At the age of twenty he finished his academical studies, and resided with his father for two years with a view to farther improvement. At this time he was invited to become private tutor to the son of sir John Hartopp, bart. at Stoke-Newington near London, and in this situation he continued for five years, gaining universal esteem, cultivating a friendship with his pupil which lasted through life, and connecting with the discharge of his office the study of the scriptures in the original languages. Although he was well qualified for the public exercise of his ministry, such was his diffidence that he would not venture to ascend the pulpit till he had completed his twenty-fourth year, at which time he was chosen assistant to Dr. Isaac Chauncy, whom he succeeded as pastor in the year 1702. His constitution was so delicate that he could not undertake the whole service, and the attack of a

fever in 1712 disqualified him for his public duties for four years. In this state of debility he was kindly received in the house of sir Thomas Abney, where the indulgent treatment of this gentleman and his lady contributed to restore his health and spirits. In this hospitable mansion he not only found a temporary asylum, but a permanent abode for the remaining thirty-six years of his life. Here he enjoyed every comfort which friendship and liberality could bestow, and which, by repairing his enfeebled frame, enabled him to resume his services in public and to prosecute his private studies, no less to the improvement and satisfaction of those with whom he was immediately connected, than to the benefit of the world; inasmuch that few persons have acquired a more extensive and a more permanent popularity, as it respects the interests both of literature and of religion. His reputation attracted the notice of both the universities of Edinburgh and Aberdeen, and they seemed to vie with each other which should first confer upon him the honour of the degree of doctor in divinity, and he received it from these two universities in the year 1728. His constitution, though in some degree renovated by the attention and kindness which he experienced, was still so delicate and feeble, that he found it necessary to remit, and at length to resign his ministerial duties; but his congregation testified their respect for him by declining to accept his offer of the renunciation of his usual salary. However, he gradually declined, and calmly expired at Stoke Newington, November the 25th, 1748, in the 75th year of his age.

Dr. Watts was a man of lively fancy, warm feelings, and a comprehensive understanding, and distinguished by that versatility of talents and pursuits, which enabled him to acquire a considerable degree of reputation in various departments of literature, but which prevented his arriving at a supereminent rank in any. The characteristic quality of his mind, manifested in his numerous productions, was a devotional spirit. Of his "*Horæ Lyricæ*," the greatest number belongs to the devotional class, and in these his ardent feelings and imagination have sometimes transported him beyond the bounds which a correct taste and sound judgment would have prescribed. The same observation may be also applied to his "*Psalms and Hymns*," and more especially to the latter, which were juvenile compositions, and in which a sober reader will be disgusted with the contrast that is exhibited between the wrath of the Supreme Being and the benignity of the Son of God; as if the Deity were inclined to punish his offending creatures with everlasting punishment, and the Son were disposed to rescue and save them. Many of the psalms and hymns, however, are admirably adapted to Christian worship, and a select collection of them, which has been lately made by some ministers in London, and which they have enriched by extracts from other sources, is less exceptionable in a variety of respects than either the psalms or hymns even of Dr. Watts in their original state; and in these devotion and poetry are more happily combined for the worship of Dissenters and even of Churchmen than in the psalmody of the establishment. Many of Watts's lyric productions possess considerable poetical merit, and display a fertility and elegance of fancy. His "*Divine Songs for Children*" have been widely circulated, and are well calculated to interest and impress youthful minds; and they are, generally speaking, unexceptionable, though not incapable of castigation and improvement.

The doctor's philosophical publications are numerous, and most of them are well known. Among these we may reckon his "*Logic*," and the supplement to it, entitled the "*Improvement of the Mind*;" "*A Discourse on Education*;" "*An Elementary Treatise on Astronomy and Geography*;"

“Philosophical Essays on various Subjects, with Remarks on Locke’s Essay on the Human Understanding;” and “A brief Scheme of Ontology.” His other works are chiefly theological, consisting of Sermons, Discourses, Essays, and Controversial Tracts, &c. His scheme of theology was undoubtedly that which is usually called orthodoxy, and, to say the least of it, approaching to Calvinism. His temper, however, was kind and gentle, and his moderation was increasing as he advanced in years, and the maturity of his judgment restrained and controlled the fervour of his feelings and passions. Some have said that towards the close of life his sentiments, with regard to the doctrine of the Trinity, were materially altered. This, however, is a question *sub judice*. Whilst it is needless in this place to enter into the dispute, and to examine the allegations *pro* and *con*, we incline to think, as far as we have had an opportunity of examining the evidence, that the supposition of some degree of change is not improbable. The printed Works of Dr. Watts, together with those which were left in M.S. for the revision of Dr. Jennings and Dr. Doddridge, were published collectively by Dr. Gibbons, in 6 vols. 4to. 1754. We shall conclude this article with the words of one of his biographers. “To whatever class Dr. Watts belongs,” ranked by this biographer among the decided advocates for orthodoxy, “he must always be regarded as one of those whose whole heart was devoted to the promotion of the best interests of mankind, and whose life would have done honour to any system of opinions.” Gibbons’s Memoirs of Watts. Johnson’s Lives of the Poets. Gen. Biog.

WATTS, in *Geography*, a town of Virginia; 30 miles N. W. of Alexandria.—Also, a town of the state of Georgia. N. lat. $34^{\circ}22'$. W. long. $86^{\circ}25'$.

WATTS *Island*, a small island in the Chesapeake. N. lat. $37^{\circ}54'$. W. long. $76^{\circ}3'$.

WATTUSKIFLET, a channel of the Baltic, between the island of Aland and the coast of Finland, abounding with small islands.

WATWEILER, or WATTERWEILER, a town of France, in the department of the Upper Rhine. Near it is a medicinal spring; 16 miles S. of Colmar.

WAU, a town of Hindoostan, in the circle of Werrear; 24 miles N. of Radunpour.

WAU-CA-HATCHO, or COW-TAIL *River*, a river of Louisiana, which is the last stream of any consequence that enters the Sabine.

WAVE, UNDA, in *Physics*, a cavity in the surface of the water, or other fluid, with an elevation on its sides. Or, it is a volume of water elevated by the action of the wind upon its surface, into a state of fluctuation.

The origin of waves may be thus conceived. The surface of a standing water being naturally plain, and parallel to the horizon, (allowing for that small degree of curvature which results from its gravitation to the centre,) if by any means it be rendered hollow, as at A, (*Plate XV. Hydraulics*, fig. 11.) its cavity will be surrounded with an elevation B B; for if a certain quantity of water be depressed below the usual level, an equal quantity must rise in some other place above that level, and the water which stands closest to the place of the original impression will of course be moved. The raised water will descend by its gravity, and, with the celerity acquired in descending, will form a new cavity; by which motions, the water will ascend at the sides of this cavity, and fill the cavity A, while there is a new elevation towards C; and, when this last is depressed, the water rises anew towards the same part. Thus arises a successive motion in the surface of the water; and a cavity, which carries an elevation before it, is moved along from A,

towards C. Thus the alternate rising and falling of the water in ridges will extend all round the original source of motion; but as they recede from that place, so the ridges, as well as the adjoining hollows, become smaller and smaller, until they vanish. This diminution of size is produced by three causes; *viz.* by the want of perfect freedom of motion amongst the particles of water, by the resistance of the air, and by the further ridges being larger in diameter than those which are nearer. It is likewise on account of the friction, or adhesion, among the particles of water, and of the resistance of the air, that, in the same place, the alternate elevations and depressions diminish gradually, until the water re-assumes its original tranquillity, unless the external impression be renewed or continued. This cavity, with the elevation next it, is called a *wave*; and the space taken up by the wave on the surface of the water, and measured according to the direction of the wave’s motion, is called the *breadth of the wave*; which is evidently equal to the distance between the tops of contiguous ridges, or between the lowest parts of two contiguous hollows; and a wave is said to *have run its breadth*, when its elevated part is arrived at the place where the elevated part of the next wave stood before, or (the situations of two contiguous waves being given) when one of them is arrived at the place of the other; and the time which is employed in this transition is called *the time of a wave’s motion*.

WAVES, *the Motion of*, forms an article in the new philosophy; and its laws being now pretty well determined, we shall give the reader the substance of what is taught on this subject.

1. The cavity, as A, is encompassed every way with an elevation; and the motion above-mentioned expands itself every way: therefore the waves are moved circularly.

2. Suppose, now, A B (*fig. 12.*) an obstacle, against which the wave, whose beginning is at C, strikes; and we are to examine what change the wave suffers in any point, as E, when it is come to the obstacle in that point. In all places through which the wave passes in its whole breadth, the wave is raised; then a cavity is formed, which is again filled up; which change while the surface of the water undergoes, its particles go and return through a small space: the direction of this motion is along C E, and the celerity may be represented by that line. Let this motion be contrived to be resolved into two other motions, along G E and D E, whose celerities are respectively represented by those lines. By the motion along D E, the particles do not act against the obstacle; but, after the stroke, continue their motion in that direction with the same celerity; and this motion is here represented by E F, supposing E F and E D to be equal to one another; but by the motion along G E, the particles strike directly against the obstacle, and this motion is destroyed: for though the particles are elastic, yet, as in the motion of the waves they run through but a small space, going backward and forward, they proceed so slowly, that the figure of the particles cannot be changed by the blow; and so are subject to the laws of percussion of bodies perfectly hard. See PERCUSSION.

But there is a reflection of the particles from another cause: the water which cannot go forward beyond the obstacle, and is pushed on by that which follows it, gives way where there is the least resistance; that is, it ascends; and this elevation, which is greater in some than other places, is caused by the motion along G E; because it is by that motion alone that the particles impinge against the obstacle. The water, by its descent, acquires the same velocity with which it was raised; and the particles of water are repelled from the obstacle with the same force in the direction E G,

as that with which they struck against the obstacle. From this motion, and the motion above-mentioned along EF , arises a motion along EH , whose celerity is expressed by the line EH , which is equal to the line CE ; and by the reflection, the celerity of the wave is not changed, but it returns along EH , in the same manner as if, taking away the obstacle, it had moved along Eh .

If from the point C , CD be drawn perpendicular to the obstacle, and then produced, so that Dc shall be equal to CD , the line HE continued will go through c ; and as this demonstration holds good in all points of the obstacle, it follows, that the reflected wave has the same figure on that side of the obstacle, as it would have had beyond the line AB , if it had not struck against the obstacle. If the obstacle be inclined to the horizon, the water rises and descends upon it, and suffers a friction, by which the reflection of the wave is disturbed, and often wholly destroyed; and this is the reason why very often the banks of rivers do not reflect the waves.

If there be a hole, as I , in the obstacle BL , the part of the wave which goes through the hole, continues its motion directly, and expands itself towards QQ ; and there is a new wave formed, which moves in a semicircle, whose centre is the hole. For the raised part of the wave, which first goes through the hole, immediately flows down a little at the sides; and, by descending, makes a cavity which is surrounded with an elevation on every part beyond the hole, which moves every way in the same manner as was laid down in the generation of the first wave.

In the same manner, a wave to which an obstacle, as AO , is opposed, continues to move between O and N , but expands itself towards R , in a part of a circle, whose centre is not very far from O . Hence, we may easily deduce what must be the motion of a wave behind an obstacle, as MN .

Waves are often produced by the motion of a tremulous body, which also expand themselves circularly, though the body goes and returns in a right line; for the water which is raised by the agitation, descending, forms a cavity, which is every where surrounded with a rising.

Different waves do not disturb one another, when they move according to different directions. The reason is, that whatever figure the surface of the water has acquired by the motion of the waves, there may in that be an elevation and depression; as also such a motion as is required in the motion of a wave.

To determine the celerity of the waves, another motion, analogous to their's, must be examined. Suppose a fluid in the bent cylindric tube EH (*fig. 13.*); and let the fluid in the leg EF be higher than in the other leg by the distance IE ; which distance is to be divided into two equal parts at i . The fluid, by its gravity, descends in the leg EF , while it ascends equally in the leg GH ; so that when the surface of the fluid is arrived at i , it is at the same height in both legs; which is the only position in which the liquid can be at rest; but by the celerity acquired in descending, it continues its motion, and ascends higher in the tube GH ; and in EF is depressed quite to l , except so much as it is hindered by the friction against the sides of the tube. The fluid in the tube GH , which is higher, also descends by its gravity, and so the fluid in the tube rises and falls, till it has lost all its motion by the friction.

The quantity of matter to be moved is the whole fluid in the tube; the moving force is the weight of the column IE , whose height is always double the distance Ei ; which distance, therefore, increases and diminishes in the same ratio with the moving force. But the distance Ei is the space to

be run through by the fluid, in order to its moving from the position EH , to the position of rest; which space, therefore, is always as the force continually acting upon the fluid: but it is demonstrated, that it is on this account that all the vibrations of a pendulum, oscillating in a cycloid, are isochronal; and, therefore, here also, whatever be the inequality of the agitations, the fluid always goes and returns in the same time. The time in which a fluid thus agitated ascends, or descends, is the time in which a pendulum vibrates, whose length is equal to half the length of the fluid in the tube, or to half the sum of the lines EF , FG , EH . This length is to be measured in the axis of the tube. See **PENDULUM.**

From these principles, to determine the celerity of the waves, we must consider several equal waves following one another immediately; as A , B , C , D , E , F , (*fig. 14.*) which move from A towards F : the wave A has run its breadth, when the cavity A is come to C ; which cannot be, unless the water at C ascends to the height of the top of the wave, and again descends to the depth C ; in which motion, the water is not agitated sensibly below the line bi : therefore, this motion agrees with the motion in the tube above-mentioned; and the water ascends and descends, that is, the wave goes through its breadth, while a pendulum of the length of half BC performs two oscillations, or while a pendulum of the length BCD , that is, four times as long as the first, performs one vibration; since the times in which pendulums of different lengths perform their vibrations are as the squares of their lengths. (See **VIBRATION.**) Therefore, the celerity of the wave depends upon the length of the line BCD ; which is greater, as the breadth of the wave is greater, and as the water descends deeper in the motion of the waves. In the broadest waves, which do not rise high, such a line as BCD does not much differ from the breadth of the wave; and in that case a wave moves its breadth, while a pendulum, equal to that wave, oscillates once. Hence, if the breadth of a wave be 39.1196 inches, (this being the length of a pendulum which vibrates seconds,) then that wave will move on at the rate of 39.1196 inches per second of time; that is, at the rate of 195 feet per minute, nearly.

In every equable motion, the space gone through increases with the time and the celerity; wherefore, multiplying the time by the celerity, you have the space gone through; whence it follows, that the celerities of the waves are as the square roots of their breadths: for as the times in which they go through their breadths are in that ratio, the same ratio is required in their celerities, that the products of the times, by their celerities, may be as the breadths of the waves, which are the spaces gone through.

Dr. Young is of opinion, that sir Isaac Newton's analogy, resulting from a comparison of a wave with the oscillation of a fluid in a bent tube, is too distant to admit our founding any demonstration upon it. LeGrange, he says, has investigated the motions of waves in a new and improved manner; and Dr. Young has also demonstrated a theorem similar to his, but, as he apprehends, more general and explicit. From these premises it appears, that, supposing the fluids concerned to be infinitely elastic, that is, absolutely incompressible, and free from friction of all kinds, any small impulse communicated to a fluid would be transmitted every way along its surface, with a velocity equal to that which a heavy body would acquire in falling through half the depth of the fluid; and he concludes, from observation and experiment, that where the elevation or depression of the surface is considerably extensive in proportion to the depth, the velocity approaches nearly to that which is thus determined,

mined, being frequently deficient one-eighth or one-tenth only of the whole. In other cases, where a number of small waves follow each other at intervals considerably less than the depth, he has endeavoured to calculate the retardation which must be occasioned by the imperfect elasticity or compressibility of the fluid; but it seems probable that the motion of small waves is still much slower than this calculation appears to indicate. Many of the phenomena of waves, says this ingenious author, may be very conveniently exhibited by means of a wide and shallow vessel, with a bottom of glass, terminated by sides inclined to the horizon; in order to avoid the confusion which would arise from the continual reflections produced by perpendicular surfaces. The waves may be excited by the vibrations of an elastic rod or wire, loaded with a weight, by means of which its motions may be made more or less rapid at pleasure; and the form and progress of the waves may be easily observed, by placing a light under the vessel, so that their shadows may fall on a white surface, extended in an inclined position. In this manner, the manifest inflection of the surface of the water may be made perfectly conspicuous.

This motion of the sea-water depends greatly on the winds, and on the situation of mountains, in regard to the sea; for the winds are driven back from these with great impetuosity; and in some places this occasions a great and very irregular undulation, beside that which is produced by the immediate action of the winds on the surface of the water in their own direct course.

Waves are to be considered as of two kinds, and these may be distinguished from one another by the names of *natural* and *accidental* waves.

The *natural* waves are those which are regularly proportioned in size to the strength of the wind, whose blowing gives origin to them. The *accidental* waves are those occasioned by the wind's reacting upon itself by repercussion from hills and mountains, or high shores, and by the washing of the waves themselves, otherwise of the natural kind, against rocks and shoals: all these causes give the waves an elevation, which they can never have in their natural state.

It seems to be pretty well determined, from a variety of experiments and observations, that the most violent wind never penetrates a great way into the water; and that in great storms the water of the sea is slightly agitated at the depth of 20 feet below the usual level, and probably not moved at all at the depth of 30 feet, or 5 fathoms; consequently the natural displacing of the waters by the wind cannot be supposed to reach nearly so low: and hence it should seem, that the greatest waves could not be so very high as they are represented by accurate and creditable navigators. Mr. Boyle found, upon inquiry, that when the wind was high, so that the waves were manifestly six or seven feet high above the surface of the water, no sign of agitation was perceived at the depth of 15 fathoms; but if the blast continued long, then the mud at the bottom was stirred, and the water became thick and dark. Persons who have remained for some time at a considerable depth have been surprised to find a storm, when they have returned to the upper parts of the water. At the depth of 12 or 15 feet, the agitation of the water has been accordingly diminished; and at a considerable distance from the shore, and in deeper water, the sea has been found proportionably calm and tranquil. It has also been found, that in a part of the sea often tempestuous, the storm did not reach with any efficacy four fathoms beneath the surface of the water. Boyle's Works, vol. iv. p. 354, 4to. Relations about the Bottom of the Sea, § 3.

Count Martigli measured carefully the elevations of the waves near Provence, and found that, in a very violent tempest, they arose only to seven feet above the natural level of the sea; and this additional foot in height, above the result of Mr. Boyle's deductions, he easily resolved into the accidental shocks of the water against the bottom, which was, in the place he measured them in, not so deep as to be out of the way of affecting the waves; and he allows that the addition of one-sixth of the height of a wave, from such a disturbance from the bottom, is a very moderate alteration from what would have been its height in a deep sea; and concludes, that Mr. Boyle's calculation holds perfectly right in deep seas, where the waves are purely natural, and have no accidental causes to render them larger than their just proportion.

In deep water, under the high shores of the same part of France, this author found the natural elevation of the waves to be only five feet; but he found also that their breaking against rocks, and other accidents to which they were liable in this place, often raised them to eight feet high.

We are not to suppose, from this calculation, that no wave of the sea can rise more than six feet above its natural level in open and deep water; for waves immensely higher than these are formed in violent tempests in the great seas. These, however, are not to be accounted waves in their natural state, but they are single waves formed of many others; for in these wide plains of water, when one wave is raised by the wind, and would elevate itself up to the exact height of six feet, and no more, the motion of the water is so great, and the succession of waves so quick, that, during the time this is rising, it receives into it several other waves, each of which would have been at the same height with itself: these run into the first wave one after the another, as it is rising; and by this means its rise is continued much longer than it naturally would have been, and it becomes accumulated to an enormous size. A number of these complicated waves arising together, and being continued in a long succession by the continuation of the storm, makes the waves so dangerous to ships, which the sailors in their phrase call mountains high. Martigli, Hist. Phys. de la Mer.

When it blows fresh, the waves not moving with sufficient rapidity, their tops, which are thinner and lighter, are impelled forward, broken, and changed into a white foam, particles of which, called the "spray," are carried a great way. Waves, with regard to their form, are circular or straight, or otherwise bent, according as the original impression is made in a narrow space nearly circular, or in a straight line, or in other configurations. In open seas the waves generally are in the shape of straight furrows, because the wind blows upon the water in a parallel manner, or at least for a long apparent tract. The same causes which raise water into waves must evidently produce the like effect on other fluids, but in various degrees, as the fluid is more or less heavy, as its particles adhere more or less forcibly to each other, and probably likewise as there is a greater or less degree of attraction between the fluid and the other body which gives it the impulse. If it be attempted to raise waves upon oil by the force of wind, it will be found very difficult to succeed in a similar degree. This difficulty is probably owing to the natural attraction of the particles of oil; and besides, there may be less attraction between oil and air than between the latter and water, for water always contains a certain quantity of air; and if it be deprived of that air by boiling, or otherwise, a short exposure to the atmosphere will enable the water to imbibe it. It is likewise probable, that the surface of water, even when stag-

nant, may not be so smooth as the surface of oil, so that the wind may more easily catch into the inequalities of the former than the latter. Hence it is that the effect of the wind upon waves may in a great degree be prevented or moderated, by spreading a thin film of oil on the surface of the water. For an account of this operation and its effects, see OIL.

WAVE-*Offering*, among the *Jews*, a sacrifice offered by agitation or waving towards the four cardinal points.

To WAVE, is used, in the *Sea-Language*, for the making signs for a vessel to come near, or keep off.

WAVED, or WAVY, a term in *Heraldry*, when a bordure, or any ordinary or charge in a coat of arms, has its outlines indented, in manner of the rising and falling of waves. This is also called *undy, undé, or ondé*, and denotes that the frist of the family in whose arms it stands, acquired his honours for sea services, and has this peculiar commemoration of it ordered in his arms.

WAVED *Hair-Grafs*, in *Agriculture*, a sort of grafs which is found to be pretty productive on mountain heathy lands, and which abounds pretty much in nutritive matter, but which loses considerably in its weight in drying, according to the trials which have lately been made on grafses at Woburn. See AIRA *Flexuosa*.

WAVELLITE, in *Mineralogy*, a mineral first discovered at Barnstaple, in Devonshire, by Dr. Wavell, and since found in various other situations. From its appearance, it has been classed by Mr. Jamefon as a member of the zeolite family. See ZEOLITE.

Wavellite occurs in a botryoidal, stalactical, and globular form; also crystallized in very oblique four-sided prisms, flatly bevelled on the extremities: the bevelling planes are set on the obtuse lateral edges. The prisms are sometimes deeply truncated on the obtuse lateral edges. Wavellite occurs also in fibres, or acicular prisms, diverging from a common centre, and either separated or adhering laterally to each other, composing hemispherical concretions of various sizes, to the magnitude of a bullet. The lustre of wavellite is pearly, more or less shining. The colour is yellowish-white, greyish-white, and greenish-white; it is translucent. This mineral is brittle, and, according to professor Jamefon, it is sufficiently hard to scratch quartz: others ascribe to it a lower degree of hardness. Before the blow-pipe it becomes soft and opaque, but neither decrepitates nor fuses. It is soluble by the assistance of heat in the mineral acids, in which it effervesces and leaves very little residue. The specific gravity of wavellite varies from 2.22 to 2.70.

The most remarkable peculiarity of this mineral is its composition; wavellite being nearly a pure hydrat of alumine; but some specimens contain a trace of fluoric acid. When fragments of the English or Irish wavellite are laid upon a glass plate, and a drop of sulphuric acid is added, the glass is slightly corroded on the application of heat, indicating the presence of the above-mentioned acid.

The constituent parts of wavellite are given as under:

Wavellite from Barnstaple.		
Alumine	- 71.50	70
Oxyd of iron	.50	
Lime	-	1.4
Water	- 28.	26.2
	100 Klaproth.	97.6 Davy.

	Cornish Wavellite.	South American Wavellite.
Alumine	- 58.70	68.
Oxyd of iron	0.19	1.
Lime	- 0.37	
Silex	- 6.12	4.50
Water	- 30.75	
Lofs	- 3.87	26.50
	100 Gregor.	100 Klaproth.

Wavellite occurs in veins in the granite of Cornwall, with fluor-spar, quartz, tin-stone, and copper pyrites. At Barnstaple, in Devonshire, it occurs in soft slate. Several mineralogists consider wavellite as a variety of the same mineral, which Hauy has called diaspore.

WAVENEY, in *Geography*, a river of England, in the county of Suffolk, which joins the Yare, at its mouth.

WAVEREN, a town of France, in the department of the Scheld, on the Dyle. By war and accidental fires much decayed; 12 miles S. of Louvain.

WAVERS, in *Rural Economy*, a term used to signify the young timber-trees, or timberlings as they are mostly called, that are left standing for further growth, in felling or cutting over woods of different kinds. See TIMBER.

WAVESON, in the *Admiralty-Law*, a term used for such goods, as, after shipwreck, appear swimming on the waves.

WAVIGNIES, in *Geography*, a town of France, in the department of the Oise; 10 miles N. of Clermont.

WAUKEAGUE, a town of the district of Maine, near the coast; 5 miles W. of New Bristol.

WAUNGLY, a town of Hindoostan, in Vissiapour; 10 miles S.E. of Currer.

WAVY, in *Botany*, is synonymous with *repandum* and *undulatum*; in the first instance, it expresses an undulating outline, with an even surface; in the second, an undulating surface, caused by the marginal region of a leaf, or petal, being more ample or luxuriant than the central part, or base. The latter is often the case with cultivated plants, as *Malva crispa*, and the different curled varieties of cabbage, brocoli, parsley, mint, &c.

WAVY, in *Heraldry*. See WAVED.

WAWAY, in *Geography*, a small island in the East Indian sea, near the E. coast of the island of Celebes, about 40 miles in circumference. S. lat. 4° 8'. E. long. 123° 30'.

WAWARSING, a large township of New York, in the south-west angle of Ulster county, 25 miles S.W. of Kingston, erected in 1806, from the S.W. part of Rochester, and lying on the W. of the Shawangunk mountain. Plumbago, of a good quality, is found in this township, and here are many indications of iron-ore. Here are several small settlements, as at Warwasing, Napenagh, and Lurenkill; but much of the land is uncultivated. Here are one Dutch reformed church, and eight or ten school-houses. In 1812, the whole population consisted of 1335 persons, and the number of electors was 117; and here were 74 looms in families, which produced 18,047 yards of cloth.

WAWIACHTANOS, Indians of America, inhabiting chiefly between the rivers Wabash and Sciota.

WAWRA, a small negro town of Africa, properly belonging to Kaarta, but when Park visited it, tributary to Maafong, king of Bambarra. It is surrounded with walls, and inhabited by a mixture of Mandingoes and Foulahs. The inhabitants are chiefly employed in cultivating corn, which they

they exchange with the Moors for salt; 60 miles E.S.E. of Benowm.

WAX, a term which comprehends two or three substances, differing in their nature and origin, and yet possessing several common properties. The common properties of the animal and vegetable productions, of which we shall give a brief account in the sequel of this article, are fusibility at a moderate heat; when kindled, burning with much flame; insolubility in water; solubility in alkalies, and also in alcohol and ether; in which two latter properties all the species of wax differ from the concrete oils, to which in other respects they bear a very strong resemblance. The most important, and most generally known and used of these substances, is

Bees' wax, excreted from the body of the bee, and employed by these insects in the construction of their cells, both for the accommodation of their young and the deposition of their honey. Of this substance, a young hive will yield at the end of the season about a pound of wax; and an old hive about twice as much. The finest wax is that which is made in dry, heathy, or hilly countries; but in parts abounding with vineyards it is decidedly inferior. Although the commonly received notion, which ascribes this substance to the elaboration of the pollen of flowers, which the bees visibly collect on their thighs, had received the sanction of observers not less distinguished than Bonnet and Reaumur (see *PAIN D'Abeilles*), yet the Lufatian Society, as long ago as the year 1768, was not unacquainted with the fact, that the wax, instead of being discharged from the mouth, is secreted in the form of thin scales among the abdominal rings or segments. In 1792, the celebrated Mr. John Hunter detected the genuine reservoir of the wax under the belly of the bees, and gave an account of his observations in the *Philosophical Transactions*, (vol. lxxxii. part 1.) On elevating the lower segments, he observed plates of a fusible substance, which he ascertained to be wax; and he was convinced, that an essential difference subsists between the pollen, which these little creatures collect with so much care and industry in the form of pellets on their thighs, and the matter of which the combs are constructed. This curious subject has been further investigated by Messrs. Huber, father and son; and they have demonstrated the organs in which the wax is secreted, though they had eluded the perspicuity of Swammerdam, Hunter, and other acute anatomists. These sacklets, or small compartments, now minutely explained and illustrated by engravings, are peculiar to the working bees, which alone produce wax; and each individual is furnished with eight of them. The waxy matter, as it occurs in a transfused state in the secretory organs, differs from the fresh wax of the combs only in being of a less compounded nature, which has been ascertained by trials with spirit of turpentine and sulphuric ether. Prosecuting these reflections, our ingenious authors concluded that the common opinion was probably erroneous; because, like Hunter, they had observed swarms, newly placed in the empty hives, construct their combs without fetching home any pollen; while the bees of old hives, where no fresh cells were required, nevertheless provided an ample stock of this powder. In order, however, to determine the point more directly, they confined a recent swarm within an empty straw-hive, leaving at their disposal only a sufficiency of honey and water for their consumption, and preventing them from going beyond the precincts of a well-closed room; when, in the short space of five days, they had constructed five cakes of a beautiful white though very fragile wax. This experiment was repeated, and was uniformly accompanied by similar results; and therefore they no longer hesi-

tated in admitting the fact, that honey, through the organic intervention of bees, may be converted into wax. In order to determine whether vegetable pollen, also, was susceptible of this conversion, the honey was wholly removed, and the confined bees were fed on fruits and pollen, of which last a large store was left at their disposal; but, though they continued in this situation during eight days, they neither made any wax, nor exhibited any plates under their abdominal rings. Having suspected that the secretion of wax originated in the cohesive principle contained in honey, our authors recurred to various experiments, which constantly proved that sugar alone was an excellent substitute for honey, and, on some occasions, afforded a superior wax. They afterwards found, that bees, when left at perfect liberty to roam abroad, act precisely on the same principle in the construction of their combs; and they also discovered, that labourers of two descriptions exist in each hive. The first, susceptible of acquiring considerable dimensions, when they have received all the honey which their stomachs can contain, are principally destined to the elaboration of the wax; while the second, whose abdomen undergoes no sensible change of bulk, neither gather nor retain more honey than is necessary for immediate subsistence, and readily share that which they collect with their companions; who take no charge of storing the hive with provisions, their appropriate office being to attend the young. These they call nursing or small bees, in contradistinction to those with dilated bellies, and which, as they say, are entitled to the appellation of "wax-workers." The existence and separate offices of these two sorts of bees were sufficiently ascertained. When the hives are filled with combs, the wax-working bees discharge their honey into the usual magazines, and produce no more wax; but, if they have no receptacle in which they can deposit it, and if the queen finds no cells formed ready for the reception of her ova, they retain in their stomachs the honey which they had amassed; and, at the end of 24 hours, the wax oozes out between the rings, when the fabrication of the combs commences. The nursing bees also produce wax, but in a much smaller quantity than the others.

As for the use of the pollen, our authors have ascertained, that it is collected for the purpose of feeding the young; and they have also found, that bees, fed too long on the syrup of sugar alone, are incapable of rearing their offspring, and at length desert the hive. The waxy matter, when newly secreted and moulded in its appropriate organs, differs from real wax in being transparent like scales of talc, white, and quite friable, or brittle; whereas that of which the cells are composed is of a yellowish-white, opaque, and flexible. Our limits will not allow our describing the processes observed by our authors with the aid of a glass apparatus, by which these insects commence and conduct the construction of their combs. The difference of aspect and consistency between cells just formed, and those which are of older standing, cannot fail to attract the attention of every observant apiarian. The former are, in fact, of a dull white colour, semi-transparent, soft, and even, without being smooth; but, in the course of a few days, the whole of their internal surface assumes a yellow tint of greater or less intensity: their sharp edges become thicker and less regular; and those tubes, which at first could not resist the slightest pressure, become flexible, somewhat more heavy, and more difficult of solution in hot water. The contour of the orifice of mature cells is bound with a rim of a reddish and odorous resin, which is also employed to cement the angles of other parts of the cell. This folder or varnish is found, on chemical trial, to be identical with the propolis, and

and quite distinct from the wax. Messrs. Huber have not only established this important fact, but detected the origin of the propolis itself. Having obtained branches of the wild poplar, cut in spring before the development of their leaves, with very large buds filled with viscous, reddish, and odorous juice, they placed these in the way of the bees to the fields, so that they must see them: soon after this arrangement, a bee alighted on one of the branches, and approached one of the largest buds; she then separated its folds with her teeth, attacked the parts which she had half-opened, pulled off filaments of the viscid matter with which they were filled, and then seized, with one of the legs of the second pair, the substance held between her jaws, brought forwards one of her hind-legs, and finally placed in the basket of that leg the little ball of propolis which she had just collected. Having accomplished this object, she again opened the bud in another place, carried off new threads of the same matter with her teeth, laid hold of them with the legs of the second pair, and placed them nicely on the other basket. She then took her departure, and re-joined her hive. In a few minutes afterwards, a second bee alighted on the same branches, and loaded herself with propolis in the same manner. This propolis was found to be different from the matter which imparts the yellow colour to the wax, which is probably secreted in the cavity of the teeth, and deposited on the wax. We observe, however, that bees are not contented with merely painting and varnishing their cells, but they also impart additional solidity to their aggregate amount by the use of a mortar, composed of wax and propolis; and which the ancients, who had not overlooked this department of their economy, termed *metis*, or *pissocerum*. (See PROPOLIS.) With the necessary documents before us, we cannot forbear introducing some further observations on the economy of these insects, though they are not immediately connected with the subject of this article. As the closeness of a hive, and the multitude of living creatures which inhabit it, (amounting sometimes to twenty-five or thirty thousand,) are circumstances which seem to preclude a free ventilation and renewal of air, we might be induced to suppose that bees are not endowed with any particular system of respiratory organs, and that they are capable of existing in any atmosphere, however vitiated. As a test of this supposition, our ingenious and persevering authors recurred to various experiments; which incontrovertibly prove, that these insects cannot long exist either in *vacuo*, or in air that is contaminated by noxious gases; that, in short, they breathe like other animals of their class; and that they are speedily deprived of life if the process of respiration be arrested. Yet it results, from eudiometrical trials, that the air of a well-stocked hive is equally pure with that of the atmosphere. It has been ascertained, too, that neither wax nor pollen favours the production of oxygen gas, and that the bees themselves have no internal faculty of generating vital air; since, if that of the atmosphere be entirely excluded, they are observed to perish in the course of a few hours. Our authors, therefore, took an opportunity of examining, whether the industry of these insects presented no particular cause of this phenomenon; and at length they were struck by the connection which might subsist between the circulation of the air and that beating of the wings which they had recently observed, and which occasioned a continual humming in the interior of their habitation. They suspected that the play of these membranes, which impress the air with sufficient force to elicit from it a very distinct sound, might be destined to replace that which had been vitiated by respiration. Although this may seem to be a trivial cause for counteracting the pernicious effect

above stated, yet by putting the hand near to a fanning-bee, we shall perceive that she agitates the air in a manner that is very sensible, and moves her wings with such rapidity as that they are scarcely distinguishable.

United at their edge by means of small hooks, the two wings of each side present a larger surface to the air, on which they have to strike; they form, besides, a slight concavity, which should somewhat contribute to increase their energy; and we may be satisfied that they describe an arc of 90° , because we see them, simultaneously, on the two extremes of their vibrations. When engaged in this exercise, the bees cling fast to the stand with their legs, the first pair being projected forwards, the second separated and fixed to the right and left of the body, while the third, closely approximated, and in a direction perpendicular to the abdomen, contributes to support the hinder parts in an elevated position. During the fine season, we may always observe a certain number of bees agitating their wings in front of the entrance to their hive; but we may also be convinced, by inspection, that still more of them are employed in fanning within their dwelling. The ordinary station of the ventilating bees is on the lower floor of the hive. All those which are occupied in this way, on the outside, have their heads turned towards the entrance, but those within present their backs to it. These bees seem to arrange themselves methodically, so that they may manage the ventilating process with the greatest ease; being distributed into files, which terminate at the entrance of the hive, and are sometimes disposed like so many diverging rays; but this order is not uniform: and it is probably owing to the necessity to which the fanning bees are subjected of leaving room for such as go and come, whose rapid course constrains them to form in file, that they may avoid being jostled and overturned at every instant. More than 20 bees may sometimes be seen ventilating in the lower part of the hive; but their number at other times is smaller; and each of them vibrates her wings for a longer or shorter period. They have been observed to continue the exertion during 25 minutes, without resting; although they seemed occasionally to take breath by suspending the vibration of their wings for an almost imperceptible instant; but, as soon as they cease from fanning, others take their place, so that the humming noise in a well-filled hive never suffers interruption.

But to return from this digression to the principal subject of the article.

Bees'-wax makes a very considerable article in commerce; the consumption of it throughout the several parts of Europe being incredible. There are two kinds, *white* and *yellow*; the yellow is the native wax, just as it comes out of the hive, after expressing the honey, &c. This colour, says Thorley, is owing to the age of the combs, and breath of the bees; wax, he says, both as it is gathered, and wrought into combs, being always white: the white is the same wax, only purified, washed, and exposed to the air. The preparation of each follows.

WAX, Yellow. To procure the wax from the combs for use; after separating the honey from them as much as possible by the press, they are either soaked for some days in clear water, in order to extract all the honey, or they are broken into pieces, and spread on a sheet near the hives, so that the bees in time suck out all the honey that is left, and reduce the wax into small fragments like bran. Then the whole of the wax is put into a large kettle, with a sufficient quantity of water; and with a moderate fire, it is melted, and then strained through a linen cloth, by a press, and thus freed from all remaining impurity. Before it is cold, they scum it with a tile, or a piece of wet wood, and cast it,

while

while yet warm, in wooden, earthen, or metalline moulds; having first anointed them with honey, oil, or water, to prevent the wax from sticking. Some, to purify it, make use of Roman vitriol, or copperas; but the true secret is to melt, scum it, &c. properly, without any ingredients at all.

The best is that of a high colour, an agreeable smell, somewhat resembling that of honey, soft, somewhat unctuous to the touch, but not sticking to the fingers, nor to the teeth when chewed. When new, it is of a lively yellow colour; it is somewhat tough, yet easy to break; by age, it loses its fine colour, and becomes harder and more brittle. In winter it becomes considerably hard and tough. It is deprived of its yellow colour and smell by exposing it in thin laminæ to the action of the light and air, in the process of bleaching; by which it becomes perfectly white, scentless, somewhat harder, and less greasy to the touch. However, wax is often sophisticated with resin, or pitch, coloured rocou, or turmeric.

The presence of resin may be suspected when the fracture appears smooth and shining, instead of being granulated: and it may be saturated by putting small pieces of the wax into cold alcohol, which will readily dissolve the resinous part, without affecting the wax in any considerable degree.

Its adulteration with earth or peas meal may be suspected when the cake is very brittle, and the colour inclining more to grey than bright pale yellow; and they may be separated by melting and straining the wax. White wax is sometimes adulterated with white oxyd of lead, in order to increase its weight. This may be known by melting the wax in water, when the oxyd falls to the bottom of the vessel.

It is also adulterated by tallow, suet, or any kind of animal fat. It then becomes more fusible, and when rebleached and exposed to a hot sun, it is very apt to cake. It likewise loses its semi-transparency, the distinguishing property of pure bleached wax. This adulteration may be detected by boiling alcohol, which will dissolve wax, but not tallow.

WAX, White. The whitening, blanching, or bleaching of wax, is performed by reducing the yellow sort, first, into little bits or grains, and melting it in a copper cauldron, with water just sufficient to prevent the wax from burning. The cauldron in which the wax is melted is so disposed, that it may flow gradually through a pipe at the bottom into a large tub filled with water, and covered with a thick cloth, to preserve the heat till the water and impurities are settled. From this tub the clear melted wax flows into a vessel, the bottom of which is full of small holes, about the size of a grain of wheat, and hence it falls in small streams upon a cylinder, constantly revolving over water, into which it occasionally dips, so that the wax is cooled, and at the same time drawn out into thin shreds or ribbands. The continual rotation of the cylinder carries off these ribbands as fast as they are formed, and distributes them through the tub. The wax, thus granulated or flatted, is exposed to the air on linen cloths, stretched on large frames, about a foot or two above the ground, in which situation it remains night and day for several days, exposed to the air and sun; and thus the yellow colour nearly disappears. In this half-bleached state, it is heaped up in a solid mass, and allowed to remain for a month or six weeks; after which, to complete the process for whitening it, it is re-melted, and ribbanded, and bleached as before, (in some cases several times) till it wholly loses its colour and smell. Some manufacturers, in re-melting it, add alum or cream of tartar, which are supposed to increase the whiteness and solidity of the wax. Some also, instead of spreading the ribbands of wax on

cloths, lay evenly a broad course of bricks, which are frequently watered, so that the wax is kept from melting by the sun's heat absorbed by the bricks.

When the sun and air have at length perfectly bleached the wax, some melt it for the last time in a large kettle; out of which they cast it, with a ladle, upon a table, covered over with little round dents or cavities, of the form of the cakes of white wax, as sold by the apothecaries, &c. having first wetted those moulds with cold water, that the wax may be the more easily got out. Lastly, they lay out these cakes to the air for two days and two nights, to render it more transparent and dry.

As the volatile sulphureous acid has the property of destroying more quickly almost all the colours of vegetables, it has been suggested by Macquer, the author of the *Chemical Dictionary*, that this bleaching might perhaps be shortened, by exposing ribbands of yellow wax to the vapour of sulphur, as is practised for wool and silk; but this process has not been found to succeed.

However, the operation of bleaching wax above described can be performed well only in fine weather, as it depends chiefly on the action of the sun. This circumstance being attended with much inconvenience to the manufacturers, the discovery of a method of whitening wax independently of the seasons would be very useful, and has been recommended to the attention of chemists by some economical societies.

With a view to discover such a method, Mr. Beckman has made experiments, an account of which is published in the fifth volume of the "*Novi Commentarii Societatis Regiæ Scientiarum Gottingensis*." According to these experiments, thin pieces of yellow wax were whitened and hardened, by being digested and boiled in diluted and undiluted nitrous acid, in a few hours. But the wax thus whitened, being melted by means of boiling water, was observed to acquire a yellow colour, less intense, however, than it was before it had been treated with the mineral acids. The marine and vitriolic acids were less effectual than the nitric or nitro-muriatic. He exposed wax to the flames of burning sulphur, but without success. Yellow wax being melted in vinegar, was rendered of a grey colour. The oil of tartar whitened wax, but less effectually than acids had done; and this wax being washed in water, and afterwards digested in nitrous acid, was rendered still more white; but upon melting it in water, a yellowish tinge returned. He liquefied wax in solutions of nitre and alum, but without any good effect. Spirit of wine, which is recommended by Mr. Boyle for this purpose, did indeed whiten the wax, but changed it to a butyraceous substance, so frothy, that its bulk was increased thirty times. Reflecting that tartar is purified from its oily particles by means of a calcareous earth, he tried the effects of a kind of fuller's earth, which he threw upon wax liquefied in water, and he agitated the mixture. This method rendered wax of a greyish colour, and is, therefore, recommended by him as preparatory to bleaching; the time necessary for which, he thinks, may be thus greatly shortened.

M. Sennebier made some remarks on the effect of light, and other supposed discolouring agents. Some yellow wax was melted, and thinly spread upon a plate of glass; and a similar plate was laid upon it when hot; and the edges of the plates were closed with sealing-wax. Thus the bees'-wax was deprived of the access of air, and it was placed in the sun, to the light of which it was exposed for four or five hours daily. Another quantity of wax was inclosed between plates in a like manner, but kept in the dark. In two days the wax exposed to the sun began to bleach, and in

in a month's time the whole, when it did not exceed one-sixth of an inch in thickness, was quite white; whilst no change at all took place in that which was kept in darkness.

Alcohol has no sensible action on wax when cold, but if the fluid be boiled, it will dissolve rather less than one-twentieth of its weight of wax; and the greater part of it separates, when cold, in the form of white bulky floculi, while the small quantity that remains is wholly precipitated by water. Such is the result of Pearson's and Bostock's experiments; whereas Fourcroy, Chaptal, and Nicholson assert, that it is insoluble in this fluid. Sulphuric ether dissolves wax when heated, and much more copiously than alcohol dissolves it, but the greater part, like that of the former, is separated by cooling, and the remainder by water. Wax boiled in caustic potash makes the fluid turbid, and in process of time rises to the surface in a flocculent form. The portion of the wax, held in solution by the clear alkaline liquor, may be separated by an acid, and the residue floating on the surface is so far converted into a saponaceous state as to have lost its inflammability, and to be no less soluble in pure water than white soap, and again precipitable by acids nearly in its original form, with a restoration of its inflammability. Pure ammonia nearly resembles the fixed alkalis in its action; but the resulting saponaceous form is less soluble in water.

When yellow wax has been long swimming in a solution of carbonate of potash, it becomes grey; and this colour is entirely changed into a milk white by subsequent digestion in nitric acid, and the wax resumes its whiteness.

If wax be distilled with a heat greater than that of boiling water, it may be decomposed. By this distillation, a small quantity of water is first separated from the wax, and then some very volatile and penetrating acid, (probably a modification of the acetous,) accompanied with a small quantity of a very fluid and very odoriferous oil. As the distillation advances, the acid becomes more and more strong, and the oil more and more thick, till its consistence be such, that it becomes solid in the receiver, and is then called *butter of wax*. When the distillation is finished, nothing remains but a small quantity of coal, which is almost incombustible, from the want of some saline matter. Wax cannot be kindled, unless it be previously heated, and reduced into vapours; in which respect it resembles fat oils. The oil and butter of wax may, by repeated distillations, be attenuated, and rendered more and more fluid, because some portion of acid is thereby separated from these substances; which effect is similar to what happens in the distillation of other oils and oily concretes; but this remarkable effect attends the repeated distillation of oil and butter of wax, that they become more and more soluble in spirit of wine; and that they never acquire greater consistence by the evaporation of their more fluid parts. Boerhaave kept butter of wax in a glass vessel open, or carelessly closed, during twenty years, without acquiring a more solid consistence. Wax, its butter, and its oil, differ entirely from essential oils and resins, in all the above-mentioned properties; and in all these perfectly resemble sweet oils. Hence Macquer concludes, that wax only resembles resins in being an oil rendered concrete by an acid; but that it differs essentially from these in the kind of oil, which in resins is of the nature of essential oils; while in wax and other analogous oily concretions, it is of the nature of sweet, unctuous oils, that are not aromatic, and not volatile, and are not obtained from vegetables by expression.

Although wax is not dissoluble at all in watery liquors,

yet the gelatinous solution obtained by boiling it in spirit of wine, by mixture with a thick mucilage of gum arabic, becomes soluble in water, so as to form therewith an emulsion or milky liquor: the wax itself is made in like manner soluble, without the intervention of spirit, by thoroughly mixing it with the gum in fine powder; but when thus dissolved, it proves still insipid, and perfectly void of acrimony.

Wax is soluble abundantly in the fixed oils, and melted with them, produces an uniform mass, the consistence of which, whatever be the proportion of each, is intermediate between the two. It is dissolved but sparingly in essential oils.

Bleached wax burns with a very pure white light, without any offensive smell, and with much less smoke than tallow; and as it is less fusible than tallow, it requires a smaller wick. (See CANDLES.) Bleached wax melts at about 155° of Fahrenheit; and the unbleached at 142° , according to Pearson and Nicholson, and also Dr. Bostock, but at 117° according to Fourcroy; whilst tallow melts at 92° , spermaceti at 133° , adipocire at 127° , and the tallow of the Chinese at 145° . (See Nicholson's Journal, vol. i. p. 70, 4to.) The specific gravity is less than that of water, being about .96.

The yellow wax is brought to market in round cakes about two inches thick; and large quantities of it are imported from the Baltic, the Levant, and the Barbary coast.

The white wax is used in the manufacture of candles, torches, tapers, figures, and a variety of other wax-works. See CANDLES, &c.

It is also an article of the *Materia Medica*, and used as an ingredient, partly for giving the requisite consistence to other ingredients, and partly on account of its own emollient quality, in plasters, cerates, and divers pomatums and unguents for the complexion.

The yellow sort, dissolved into an emulsion, or mixed with spermaceti, oil of almonds, conserve of roses, &c. into the form of an electuary; or divided, by stirring into it, when melted over a gentle fire, as much as it will take up of powdery matter, as the compound crab's-claw powder, has been given also internally, and, as some have pretended, often with great success, in diarrhoeas and dysenteries, for obtunding the acrimony of the humours, supplying the natural mucus of the intestines, and healing their excoriations or erosions.

The empyreumatic oil, into which wax is resolved by distillation with a strong heat, is greatly recommended by Boerhaave and others, for healing chaps and roughness of the skin, for discussing chilblains, and with proper fomentations and exercise, against stiffness of the joints, and contractions of the tendons. It is, without doubt, says Dr. Lewis, highly emollient; but does not appear to have any other quality by which it can act in external applications; it has nothing of the acrimony or pungency which prevail in all the other known distilled vegetable oils; though in smell it is not a little disagreeable and empyreumatic; a circumstance which occasions it to be at present more rarely used than formerly. As the wax swells up greatly in the distillation, it is convenient to divide it, by melting it with twice its weight of sand; or putting the sand above it in the retort, that it may mingle with the wax when brought into fusion. The oil, which is preceded by a small quantity of acid liquor, congeals in the neck of the retort, from whence it may be melted down, by applying a live coal, and made fluid by redistilling it two or three times without addition. The fæces remaining, after expressing the wax, have been used

used both by surgeons and farriers, with success, against frins.

The officinal preparations are as follow: *cera flava purificata* of Dub. Ph.; *oxidum antimonii vitrificatum* *cera* of Edinb.; *emplastrum cereæ* of Lond. and Edinb.; *emplastrum cumini* of Lond.; *empl. picis compositum* of Lond.; *empl. oxidi ferri rubri* of Edinb.; *empl. affa fatidæ* of Edinb.; *empl. gummosum* of Edinb.; *empl. meloes vesicatorii* of Edinb. and Lond.; *empl. galbani* of Dub.; *empl. aromaticum* of Dub.; *ceratum* of Lond. and Dub.; *ceratum calaminæ* of Lond. and Dub.; *ceratum resinæ* of Lond. Edinb. and Dub.; *ceratum sabinae* of Lond. and Dub.; *ceratum saponis* of Lond.; *unguentum picis aridæ* of Lond. and Edinb.; *ung. infusi meloes vesicatorii* of Edinb.; and *ung. cantbaridis* of Dub. Ph. For the first, see *white-wax* below. The second, or vitrified oxyd of antimony with wax, formerly waxed glafs of antimony, is formed by melting one part of yellow wax in an iron vessel, and throwing into it eight parts of oxyd of antimony vitrified with sulphur, reduced to powder, and roasting the mixture with a gentle fire for a quarter of an hour, stirring it assiduously with a spatula; then pouring out the latter, and when cold rubbing it into a powder. This preparation is diaphoretic and cathartic, occasionally exciting nausea and vomiting. It was formerly thought to possess efficacy in diarrhœa and dysentery; but is now scarcely ever prescribed. The dose may be from gr. ij. to gr. xv. given twice or three times a day. For the *empl. cereæ*, see *Wax PLASTER*. For the 4th, see *EMPLASTRUM é Cymino*. For the 5th, see *Compound Pitch PLASTER*. For the 6th, see *PLASTER of red Oxyd of Iron*. For the 7th, see *Affa Fatida PLASTER*. For the 8th, see *Gum PLASTER*. For the 9th, 10th, and 11th, see *PLASTER*. For the others, comprehending *cerates* and *ointments*. See *UNGUENTUM*.

The *bleached* or *white wax* is generally melted and cast, in the manner already stated, into thin discs, about 5 inches in diameter, in which form it is found in the shops. For medical purposes, it is regarded as a demulcent; and has been sometimes administered in obstinate cases of diarrhœa and dysentery, with the view of sheathing the bowels; which effect is better produced by simple mucilages and solutions. It is generally exhibited dissolved in mucilaginous fluids by means of soap, in the proportion of 3d part of the wax, with which it is first melted, and then rubbed in a mortar, with the fluid gradually added; but a preferable method is said to be that of Poerner, which is first to melt the wax with olive oil, and then mix the oily compound while hot with the mucilaginous fluid, by triturating with the yolk of an egg. The dose is a cupfull of the emulsion, containing about ℥j of wax, given every four or five hours. This wax, as well as the yellow sort, is much used in the composition of plasters and ointments. The officinal preparations are *ceratum cetacei* of Lond. Edinb. and Dub. pharmacopeias; *unguentum cetacei* of Lond. and Dub.; *ung. hydrargyri nitrico-oxydi* of Lond.; *linimentum simplex* of Edinb.; and *ung. simplex* of Edinb. See *CERATUM*, *LINIMENT*, and *UNGUENT*. Lewis's Mat. Med.

Yellow wax is made soft with turpentine, yet retains its natural colour. Red wax is only the white melted with turpentine, and reddened with vermilion or alkanet. Verdigrise makes it green; and burnt paper, or lamp-black, black. Some travellers tell us of a natural black wax; assuring us there are bees, both in the East and West Indies, that make an excellent honey, included in black cells. Of this wax, they say, it is, that the Indians make those little vases, in which they gather their balsam of Tolu.

WAX is also produced by the secretion of many plants,

and forms the silvery powder or bloom, which covers their leaves and fruit. It is found very abundantly combined with resin, covering the trunk of the wax-palm (*Cerokylon*) of South America, found in the Quinoliu mountains, 180 feet high, with leaves 20 feet long, the trunk of which is covered with the waxy secretion about two inches thick, and consisting of two-thirds of resin and one of wax; and very pure, encrusting the seeds of the *Myrica cerifera*, or wax-tree of Louisiana, and other parts of North America. The *Pe-la* of the Chinese is an animal wax, and the white lac of India appears to be a variety of wax; so that wax may be regarded, in the extended meaning of the term, both as an animal and a vegetable product. The croton sebiferum, the tomex sebifera, the poplar, the alder, the pine, as well as the Myrica, afford a concrete inflammable matter by decoction, that more or less resembles tallow or wax, that is, a fixed oil saturated with oxygen. But the Myrica cerifera supplies it in the greatest abundance. The grains of this tree, and the shining wax obtained by boiling them in water, have been long ago, viz. in 1722 and 1725, noticed in the History of the Academy of Sciences. The wax, it was observed, is drier and more friable than our's; and it was found, that the liquor in which the grain had been boiled, and from which the wax was procured, afforded, on evaporation, a kind of extract that checked the most obstinate dysenteries; and the inhabitants of Louisiana are said to have made candles of the wax. Several authors have mentioned different species of these trees; but the wax they afford has more lately been the subject of experimental investigation, particularly by M. Cadet and Dr. Bostock. The most fertile of these shrubs afford near seven pounds of berries, the gathering of which employ several families. These berries are thrown into a kettle, and covered with water. Whilst the water is boiling, the grains are stirred about against the sides of the vessel, so that the wax may more easily come off. In a little time it floats on the water like fat, and being collected, is strained through a coarse cloth, to free it from any impurities. This operation is repeated with fresh berries; and when a considerable quantity of wax has been obtained, it is laid upon a cloth to drain off the water; and it is then dried and melted a second time; and when thus purified, formed into masses. Four pounds of berries afford about one of wax: that which is first obtained is generally yellow; but in the latter boilings it assumes a green colour, from the pellicle with which the kernel of the berry is covered. M. Cadet made a variety of experiments on these berries, and found that the powder which was obtained from them afforded an astringent solution by alcohol, and that it contained gallic acid, but no tannin; and to this acid he attributes their effect in dysenteries. The wax, obtained either by the decoction of the grains, or the solution of the powder when precipitated from alcohol by water, when melted, is always of a greenish-yellow; of a firmer consistence than bees'-wax, dry, and sufficiently friable to be pulverized; and evidently more oxygenated than the wax prepared by bees. Candles made of this wax yielded a white flame, a good light, without smoke, and without guttering; and when quite fresh, they emit a balsamic odour, considered in Louisiana as very salutary to persons in bad health. Distilled in a retort, this wax, for the most part, passes over in the form of butter. This portion is much whiter, and has no more consistence than tallow. Another portion that was decomposed afforded a little water, with some empyreumatic oil and sebatic acid. Much carbonated hydrogen gas and carbonic acid gas were disengaged; and there remained in the retort a black and coaly bitumen. Ether was found to dissolve

this wax better than alcohol. Oxygenated muriatic acid rendered this, as well as bees'-wax, perfectly white; but the vegetable wax was bleached with the greatest difficulty. The solution in ammonia is of a brown colour, and a portion of the wax is rendered soapy; and it forms soap with fixed alkali. When the soap of Myrica is decomposed, a very white wax is obtained, but in a state unfit for our uses. Litharge dissolves very well in this melted wax, and forms a hard plaster, the consistence of which may be diminished at pleasure by the addition of a little oil. For bleaching this wax, M. Cadet observes, that two re-agents present themselves to manufacturers, the sulphuric acid and the oxygenated muriatic acid. He proposes the following method as the most speedy in its effect:—Let the wax be reduced to a very divided state, and stratified in a cask with superoxygenated muriate of lime, and let them remain for some time in contact without water. Let the salt be afterwards decomposed with water, acidulated by the sulphuric acid; taking care to pour the water a little at a time at different intervals, until there shall be no longer any perceptible disengagement of muriatic gas; at which period a large quantity of water is to be added, and the mixture agitated with a staff. The insoluble sulphate of lime falls down by repose, while the bleached wax rises and swims at the surface. This is to be washed and melted on the water bath. Our author closes his memoir with recommending the culture of the plant that yields this wax, and with a brief detail of methods for effecting this purpose. Dr. Bostock has also prosecuted an inquiry into the nature and uses of myrtle wax. He finds that in its more important properties it resembles bees'-wax, but that in some respects they differ from one another. The myrtle wax is moderately hard and consistent, possessing in part the tenacity of bees'-wax, without its unctuousity, and also, in some degree, the brittleness of resin. The prevalent colour is pale green, tending in most of the pieces to a dirty grey; in others it is lighter, more transparent, and of a yellowish tinge. Its specific gravity is about 1.0150, water being 1.000, so that it sinks in it, and the white bees'-wax being .9600. Water has no action upon it, either when cold or at the boiling heat. Alcohol, when cold, does not affect it; but 100 parts, by weight, of this fluid, when boiling, dissolve about five parts of the wax. Nearly four-fifths are deposited by the cooling of the alcohol; one-fifth remains suspended, but in the course of a few days is slowly deposited, or may be precipitated by the addition of water. Sulphuric ether, when at the common temperature of the atmosphere, dissolves only a small quantity of this wax, but acts upon it rapidly when boiling. It takes up somewhat more than one-fourth of its own weight. As the ether cools, it is mostly separated, and the small residue may be precipitated by water. After solution, the wax is nearly colourless, and the fluid assumes a beautiful green hue. The deposit by evaporation somewhat resembles spermaceti. Rectified oil of turpentine, at the temperature of the atmosphere, softens the wax, but does not dissolve it: aided by a moderate heat, 100 grains of the turpentine dissolves six grains of the wax. The turpentine acquires a light green tinge, part of the wax is separated as the fluid cools, and part remains permanently dissolved in it. Pure potash renders it colourless by boiling, and forms a soap with a small part, which being decomposed by acid, affords the wax nearly unchanged. Pure ammonia acts nearly as potash, but more feebly. The three principal mineral acids act upon the myrtle wax, but with no great force. The sulphuric acid, with a moderate heat, dissolves about one-twelfth of its weight, and converts it into a thick, dark-brown mass, which on cooling becomes nearly con-

crete, but without any separation of the wax. The nitric and muriatic acids, even when heated, seem to possess little attraction for the wax. From such experiments, Dr. Bostock assigns to myrtle wax, with a considerable degree of probability, the place which it should occupy among chemical substances. Its inflammability, fusibility, insolubility in water, and the action which takes place between it and the alkalies, indicate its affinity to the fixed oils; while its texture and consistence, and more particularly its habitudes with alcohol and ether, manifest a resemblance to the resins. Upon the whole, we may consider the myrtle wax as a fixed vegetable oil, rendered concrete by the addition of a quantity of oxygen; and seeming to hold the same relation to the fixed, which resins do to the essential oils of vegetables. Dr. Bostock has instituted a comparison between myrtle wax and other substances which it resembles, such as bees'-wax, spermaceti, adipocire, and the crystalline matter of biliary calculi; and, upon the whole, deduces this conclusion, that though these five substances possess certain properties in common, and have a degree of similarity in their external appearance, yet that they differ materially in their chemical nature. There is indeed, he says, reason to conjecture, that they are all composed of the same elements, combined together in different proportions, and with different degrees of attraction. Nicholson's Journal, vol. iv. 8vo.

WAX, *Chafe*. See CHAFE.

WAX, *Crude* or *Rough*, called by the French *cire brute*, in *Natural History*, a name given to a substance called by the ancients *erithace*, *fundarac*, and *ambrosia*.

We seem to have no name for it in English, but may call it after the name of the French, *rough wax*.

The Dutch call it the food of the bees, and that, perhaps, very properly, there appearing many reasons to think that the bees eat it.

This is the yellow substance found on the hinder legs of bees in small lumps, of which, as Reaumur and some others erroneously thought, wax is made by this insect. See PAIN *d'Abeilles*.

WAX, *Myrtle*. See MYRICA, and WAX, *supra*.

WAX, *Virgin*, *Propolis*, is a sort of reddish wax, used by the bees to stop up the clefts or holes of the hive. It is applied just as taken out of the hive, without any art, or preparation of boiling, &c. It is the most tenacious of any, and is held good for the nerves. See PROPOLIS.

WAX, *Sealing*, or *Spanish Wax*, is a composition of gum lacca, melted and prepared with resins, and coloured with some suitable pigment.

There are two kinds of sealing-wax in use: the one hard, intended for sealing letters, and other such purposes, where only a thin body can be allowed; the other soft, designed for receiving the impressions of seals of office to charters, patents, and such written instruments.

The best hard red sealing-wax is made by mixing two parts of shell-lac, well powdered, and resin and vermilion, powdered, of each one part, and melting this combined powder over a gentle fire; and when the ingredients seem thoroughly incorporated, working the wax into sticks. Seed-lac may be substituted for the shell-lac; and instead of resin, boiled Venice turpentine may be used. A coarser, hard, red sealing-wax may be made, by mixing two parts of resin, and of shell-lac, vermilion and red-lead, mixed in the proportion of one part of the vermilion to two of the red-lead, of each one part; and proceeding, as in the former preparation. For a cheaper kind, the vermilion may be omitted, and the shell-lac also, for very coarse uses. The hard black sealing-wax may be prepared in the same manner;

uing

using for the best sort, instead of the vermilion, the best ivory black; and for the coarser sort, instead of the vermilion and red-lead, the common ivory black. For hard green sealing-wax, instead of vermilion, use powdered verdigrise; and for a bright colour, distilled, or crystals of verdigrise. For hard blue sealing-wax, instead of the vermilion, substitute well powdered smalt, or for a light blue, verditer; or a mixture of both. For yellow hard sealing-wax, substitute masticot, or, for a bright colour, turbitth mineral, instead of the vermilion. The hard purple wax is made like the red; changing half the quantity of the vermilion for an equal, or greater proportion of smalt, as the purple is desired to be more blue or more red.

For uncoloured soft sealing-wax, take of bees'-wax, one pound; of turpentine, three ounces; and of olive oil, one ounce; place them in a proper vessel over the fire, and let them boil for some time; and the wax will be then fit to be formed into rolls or cakes for use. For red, black, green, blue, yellow, and purple soft sealing-wax, add to the preceding composition, while boiling, an ounce or more of any ingredients directed above for colouring the hard sealing-wax, and stir the mass, till the colouring ingredient be incorporated with the wax.

The hard sealing-wax is formed into sticks, by rolling the mass on a copper-plate, or stone, with a rolling-board, lined with copper, or block-tin, into rolls of any required size. In order to give them the fire-polish, or gloss, a furnace or stove, like a pail, with bars at the bottom for supporting the charcoal, and notches at the top of the sides for putting the sticks of wax over the fire, is usually provided. By means of this stove the sticks of wax may be conveniently exposed to the fire, and turned about, till the wax is so melted on the surface as to become smooth and shining. Hard sealing-wax may be formed into balls, by putting a proper quantity on the plate or stone, and having fashioned it into a round form, rolling it with the board till it be smooth.

The soft wax is easily formed into rolls or cakes, by pouring the melted mass of the ingredients, as soon as they are duly prepared, into cold water, and working it with the hands into any desired figure. Some perfume both these kinds of wax, by using, for a pound of the wax, half an ounce of benjamin, one scruple of oil of Rhodium, ten grains of musk, and of civet and ambergrise, each five grains; rubbing the oil with the other ingredients powdered; and when the wax is ready to be wrought into sticks, sprinkling in and well stirring the mixture; or by using one ounce of benjamin, one scruple and a half of oil of Rhodium, and five grains of ambergrise, in the same manner. Lewis's Com. of Arts, p. 370. Handmaid to the Arts, vol. ii. p. 34, &c.

WAX-Candles. See CANDLE.

WAX, *To imitate Fruit, &c. in.* Take the fruit, and bury it half-way in clay; oil its edges, and the extant half of the fruit; then nimbly throw on it tempered alabaster, or plaster of Paris, to a considerable thickness. When this is concreted, it makes the half mould, the second half of which may be obtained in the same way. The two parts of the mould being joined together, a little coloured wax, melted, and brought to a due heat, being poured through a hole made in any convenient part of the mould, and presently shook every way therein, will represent the original fruit. Boyle's Works abr. vol. i. p. 136.

Here we must not forget that pretty invention of M. Benoit, a man famous at Paris for his figures of wax. Being by profession a painter, he found the secret of forming moulds on the faces of living persons, even the fairest and most delicate, without any danger either to their health or

complexion: in which moulds he cast masks of wax; to which, by his colours, and glass eyes imitated from nature, he gave a sort of life: inasmuch as, when clothed in proper habits, they bore such a resemblance, that it was difficult distinguishing between the copy and the original.

WAX, *Gilding.* See GILDING.

WAX, *Grafting,* is a composition serving to bind or fix the bud, or graft, in the cleft of the stock.

Instead of grafting wax, the country gardeners, &c. only use clay, over which they lay a piece of linen cloth, and so keep it moist; and to prevent its cracking with the heat of the sun, they tie moss over it. But the wax ordinarily used is a compost of one pound and a half of pitch, a quarter of a pound of wax, and an ounce of oil of almonds, melted and mixed together: with the addition, in spring or autumn, of a moderate quantity of turpentine.

For cleft-grafting, whip-grafting, and grafting by approach, Mr. Mortimer recommends tempered clay, or soft wax; but for rind-grafting, clay and horse-dung.

WAX, *Green.* See GREEN Wax.

WAX, *thorough,* in Botany. See BUPLEURUM.

WAX, *Painting in.* See ENCAUSTIC Painting.

WAX-Bill. See LOXIA *Afrillid.*

WAX-Scot, or Wax-shot, *Ceragium*, in our *Ancient Customs*, money paid twice a year towards the charge of maintaining lights, or candles, in the church.

WAXENBURG, in *Geography*, a town of Austria; 10 miles W. of Freyftadt.

WAXHOLM, a fortress on the coast of Sweden, in the Baltic; situated on a small island at the entrance of the channel of the Malar Lake, and built in the year 1649. It has since been greatly improved and enlarged, so that it has the appearance of a little town. Here all homeward-bound ships are searched. On this island, which is called *Waxon*, besides this fort, are a church, a school, and a custom-house. The chief occupation of the inhabitants is fishing; 16 miles E. of Stockholm. N. lat. 59° 21'. E. long. 18° 16'.

WAXING, *CERATIO*, in *Chemistry*, the preparation of any matter to render it fit and disposed to liquefy, or melt, which of itself it was not.

This is frequently done, to enable things to penetrate into metals, or other solid bodies.

WAXING, in the *Manufacture of Calico*, &c., a process by which the operation of certain colours is resisted by stopping out with wax; but it is too expensive to be often adopted among calico-printers, who are anxious to finish their prints with the least possible charge. Formerly this mode was very generally practised, and great quantities of wax were consumed in the process. In the East Indies wax is still used for preserving the whites in calico-printing. In printing the silk handkerchiefs called bandanas, a process called *waxing* is still followed. It consists in making a preparation of tallow and rosin very liquid by heat, and in printing it in that state with a block upon the silk. When such goods are passed through the blue vat, those parts which are covered with the tallow and rosin are preserved from the action of the indigo, and remain white, while the whole remainder is dyed a fast blue. The method afterwards taken to discharge a part of this blue, and produce yellow, orange, &c. is as follows:—The agent employed for this purpose is the nitrous, and sometimes the nitro-muriatic acid. This was used for the purpose of putting yellow figures upon blue silk handkerchiefs. With this view aqua fortis, or nitro-muriatic acid, of a strength suitable to the kind of blue that is to be discharged, is mixed either with gum-tragacanth, or with flour paste, to a proper consistence, and in this form it is printed on the silk, by means of a common block, on which

the intended pattern is cut. The consequence of this is, that wherever the acid attaches, there the original colour is discharged, and a yellow dye is produced in its place. The pieces are then steamed, by passing them over a vessel containing boiling water, which gives brilliancy to the colour, and finishes the operation. Parkes's Ess. vol. ii. p. 149. 170. See *Discharge Work*, and *DISCHARGING of Colours*.

WAXWAY, in *Geography*, an island in the East Indian sea, near the E. coast of the island of Celebes, about thirty miles in circumference. S. lat. $3^{\circ} 35'$. E. long. $123^{\circ} 15'$.

WAY. See *PULO Way*.

WAY, *Via*. See *HIGHWAY*, *ROAD*, *TURNPIKE*, and *VIA*.

Roman ways are divided into *consular*, *praetorian*, *military*, and *public*. See *VIA*.

We have four notable ones of these in England; anciently called *chimini quatuor*, and intitled to the privileges of *pax regis*. The first is *Wailing-street*, or *Watheling-street*, leading from Dover to London, Dunstable, Towcester, Atterston, and the Severn, near the Wrekin in Shropshire, extending as far as Anglesea in Wales. The second, called *Hekineld*, or *Ikenild-street*, reaches from Southampton, over the river Isis at Newbridge, thence by Camden and Litchfield, then passes the Derwent near Derby, so to Bolsover-castle, and ends at Tinmouth. The third, called *Fosse-way*, because in some places it was never perfected, but lies as a large ditch, leads from Cornwall through Devonshire, by Tetbury near Stow in the Wolds; and beside Coventry to Leicester, Newark, and so to Lincoln. The fourth, called *Erming*, or *Erminage-street*, stretches from St. David's in West Wales, to Southampton.

WAY. See *WEIGH*.

WAY, *Milky*. The opinion, long maintained among astronomers, but lately controverted, that the milky way contains a great number of stars, has been confirmed by the observations of the ingenious and indefatigable Dr. Herschel. On applying his telescope of the Newtonian form, with an object-speculum of twenty feet focal length and an aperture of $18\frac{7}{10}$ inches, to a part of this space, he found that it completely resolved the whole whitish appearance into small stars; which his former telescopes had not light enough to effect. In the tract immediately about the hand and club of Orion, to which his observations were particularly directed, the multitude of stars of all possible sizes that presented themselves to view was astonishing: and in order to form some just idea of their number, Dr. Herschel counted many fields, and computed from a mean of them, what a given portion of the milky way might contain. Among many trials of this sort, he found that six fields, promiscuously taken, contained 110, 60, 70, 90, 70, and 74 stars each. A mean of these gives 79 stars for each field. Hence, by allowing fifteen minutes of a great circle for the diameter of the field of view, it is inferred, that a belt of fifteen degrees in length and two in breadth, which is the quantity often observed by this excellent astronomer to pass through the field of his telescope in one hour's time, could not well contain less than fifty thousand stars, that were large enough to be distinctly numbered. But, besides these, Dr. Herschel suspected at least twice as many more, which, for want of light, he could only see now and then by faint glittering and interrupted glimpses. See *GALAXY* and *NEBULA*.

WAY of a Ship is sometimes used for the same with the *rake*. But the term is more commonly understood of the course or progress which she makes on the water under sail: thus, when she begins her motion, she is said to be *under way*; when that motion increases, she is said to have *fresh way* through the water; when she goes apace, they say *she*

has a good way; and they call the account how fast she sails by the log, *keeping an account of her way*.

And because most ships are apt to sail a little to the leeward of their true course; they always, in casting up the log-board, allow something for her leeward-way. Hence also a ship is said to have *bead-way* and *stern-way*.

WAY of the Rounds, *Chemin des Rondes*, in *Fortification*, is a space left for the passage of the rounds, between the rampart, and the wall of a fortified town.

This is not now much in use; because the parapet not being above a foot thick, it is soon overthrown by the enemy's cannon.

WAY, *Covert*, *Foss*, *Gang*, *Hatch*, *Spur*, and *Water*. See the several articles.

WAY-Bread, in *Agriculture*, a name given in some places to the herb plantain, which is very useful in some grass lands, as increasing the quantity of feed very greatly. See *PLANTAGO*.

WAY-Going Crop, a term applied to that which is taken from the ground the year the tenant or occupant leaves a farm. Such crops are regulated in many different ways, according to the nature of the leases. See *LEASE*.

WAY-Leave, a provincial term for the ground purchased or hired to make a waggon-way upon, between coal-pits and the river.

WAY-Pane, in *Agriculture*, a term applied to the slips left for cartage in watered lands. It is that part of the ground which lies, in a properly watered meadow, on that side of a main where no trenches are formed and taken out, but is floated all the length of the main over its banks, having a drain parallel to it. It serves as a road for conveying the hay upon out of the ground, instead of the teams having to cross all the trenches.

WAY-Thistle, a troublesome plant of the perennial weed kind, with strong roots that branch out in a horizontal manner. Some think it may be weakened or destroyed wholly by frequent cutting over, the best season for which is when it is coming into full bloom; as the wet then gets down its hollow stalk, and aids the rotting of it. In tillage-land it is sometimes got quit of by deep repeated ploughing. See *THISTLE* and *WEEDS*.

WAY-Warden, in *Rural Economy*, a name sometimes given to the surveyor or overlooker of the roads of a district or county.

WAYA, in *Geography*, a town on the E. coast of the island of Celebes, in Tolo bay. S. lat. $1^{\circ} 50'$. E. long. $121^{\circ} 52'$.

WAYAM, a small island in the Pacific ocean, near the S.E. coast of the island of Waygoo. S. lat. $0^{\circ} 24'$. E. long. $131^{\circ} 30'$.

WAYBARI, a river of Guiana, which runs into the Atlantic, N. lat. $6^{\circ} 25'$. W. long. $58^{\circ} 6'$.

WAYBORN HOPE, a creek and point of land, on the N. coast of the county of Norfolk, which takes its name from a village, about five miles from Holt.

WAYED HORSE, in *Rural Economy*, a term applied to an animal of this kind which has been already backed and broken in for work, and which shews a disposition to be tractable and useful. See *HORSE* and *TEAM*.

The term is likewise sometimes applied to team-oxen and other animals.

WAYFARING-TREE. See *VIBURNUM*.

WAYGAT'S STRAIT, in *Geography*, a strait of Russia in Europe, separating a small island, called *Waygat* island, from the continent or country of the Samoiedes. It is also called *Vaigatskoi* and *Vaiatch*. N. lat. 68° . E. long. 60° . See *VAIGATSKOI*.

WAYGOO, an island in the Pacific Ocean, about 60 miles

miles in length, from E. to W., and 25 in breadth. N. lat. $0^{\circ} 2'$ to $0^{\circ} 30'$. E. long. $130^{\circ} 31'$ to $131^{\circ} 40'$.

WAYNE, a town of America, in the district of Maine, and county of Kennebeck, containing 819 inhabitants.—Also, a township of Pennsylvania, in Greene county, containing 588 inhabitants.—Also, a township of Pennsylvania, in Crawford county, containing 502 inhabitants.—Also, a township of Pennsylvania, in Mifflin county, containing 1501 inhabitants.—Also, a county of Pennsylvania, containing 4125 inhabitants.—Also, a township of Ohio, in the county of Adams, containing 901 inhabitants.—Also, a township of Ohio, in the county of Butler, containing 1135 inhabitants.—Also, a township of Ohio, in the county of Columbiana, containing 377 inhabitants.—Also, a township of Ohio, in Jefferson county, containing 1161 inhabitants.—Also, a township of Ohio, in Knox county, containing 478 inhabitants.—Also, a township of Ohio, in Montgomery county, containing 431 inhabitants.—Also, a township of Ohio, in Pickaway county, containing 742 inhabitants.—Also, a township of Ohio, in Scioto county, containing 398 inhabitants.—Also, a township of Ohio, in Tuscarawa county, containing 191 inhabitants.—Also, a township of Ohio, in Warren county, containing 1862 inhabitants.—Also, a county of Kentucky, containing 5393 inhabitants, of whom 226 are slaves; the town Monticilio contains 37 persons, including 4 slaves.—Also, a county of North Carolina, containing 8687 inhabitants, 2756 being slaves.—Also, a county of Georgia, containing 254 inhabitants.—Also, a county of the Mississippi territory, containing 1253 inhabitants, 262 being slaves.—Also, a large township of New York, in the N.E. part of Steuben county, 15 miles E. of Bath, called Frederick's town till the year 1808: it has a post-office called Roscommon. The S. part is hilly, but the central and other parts are arable and productive. The timber is chiefly oak and walnut, and some pine on the hills. Here are a congregation of Baptists, and a competent number of school-houses. The settlement commenced about 1794, and the population is rapidly increasing. In 1810, the number of people was 1025, and that of senatorial electors 57.

WAYNESBOROUGH, a town of Georgia, containing 111 inhabitants.

WAYS and MEANS, *Committee of*. See SUPPLIES.

WAYTE, in *Geography*, a rocky islet in the straits of Macassar, near the west coast of Celebes. S. lat. $0^{\circ} 40'$. E. long. $119^{\circ} 18'$.

WAYTO, a town on the S.E. coast of the isle of Timor. S. lat. $8^{\circ} 30'$. E. long. $126^{\circ} 9'$.

WAY-WISER, an instrument for measuring the road, or distance gone; called also perambulator, and podometer, or pedometer.

Mr. Lovell Edgworth communicated to the Society of Arts, &c. an account of a way-wiser of his invention; for which he obtained a silver medal. This machine consists of a nave, formed of two round flat pieces of wood, one inch thick and eight inches in diameter. In each of these pieces there are cut eleven grooves, five-eighths of an inch wide and three-eighths deep; and when the two pieces are ferewed together, they enclose eleven spokes, forming a wheel of spokes, without a rim: the circumference of the wheel is exactly one pole; and the instrument may be easily taken to pieces, and put up in a small compass. On each of the spokes there is driven a ferril, to prevent them from wearing out; and in the centre of the nave, there is a square hole to receive an axle. Into this hole there is inserted an iron or brass rod, which has the thread of a very fine screw worked upon it from one end to the other; upon this screw

hangs a nut which, as the rod turns round with the wheel, advances or recedes towards or from the nave of the wheel. The nut does this because it is prevented from turning round with the axle, by having its centre of gravity placed at some distance below the rod, so as always to hang perpendicularly like a plummet. Two sides of this screw are filed away flat, and have figures engraved upon them to shew by the progressive motion of the nut, how many circumvolutions the wheel and its axle have made: on one side the divisions of miles, furlongs, and poles, are in a direct, and on the other side the same divisions are placed in a retrograde order.

If the person who uses this machine places it at his right side, holding the axle loosely in his hands, and walks forward, the wheel will revolve, and the nut advance from the extremity of the rod towards the nave of the wheel. When two miles have been measured, the nut will have come close to the wheel. But to continue this measurement, nothing more is necessary than to place the wheel at the left hand of the operator; and the nut will, as he continues his course, recede from the axle-tree, till another space of two miles is measured.

It appears from the construction of this machine, that it operates like circular compasses; and does not, like the common-wheel way-wiser, measure the surface of every stone and mole-hill, &c. but passes over most of the obstacles it meets with, and measures the chords only, instead of the arcs of any curved surfaces upon which it rolls.

WAYWODE. See WAIWODE.

WEACHIN, in *Botany*, the name given by the Indians of America to the maize, or Indian corn, which they cultivated for bread before we knew them.

WEADINGSTEDE, in *Geography*, a town of the duchy of Holstein; 7 miles E. of Wessingburen.

WEAK, or EASY BRANCH, in the *Manege*. See BANQUET, and BANQUET-Line.

WEAK-Land, in *Agriculture*, that which is of a light, thin, open nature, and which is deficient in staple, or the quantity of proper mouldy material. It is directly contrary to that of the cold watery kind, which often changes the nature and quality of the produce, and retards vegetation in the early spring, or during wet seasons, as it forwards the growth of the crops that are put upon it, but is frequently defective in the amount of produce which is afforded. It is to be improved by the use of proper earthy substances and manures, according as the quality of it may be, and by keeping the surface of it as much covered as possible by suitable green crops, to prevent the too great exposure of it to the action of the sun and winds. Such other means, of the same kind, as the nature, circumstances, and situation of the land will permit, may likewise be pursued. See SOIL.

WEAK-Pulse. See PULSE.

WEAKY, in *Agriculture*, a term used to signify juicy, in contradistinction to that of dry or husky, as applied to different kinds of food.

WEALD, or WEALD-Land, a name applied to a kind of wild woody tract of ground of a stiff heavy quality in some southern districts, as those of Kent, Suffex, &c.

It is mostly of a deep tenacious clayey, marly, and loamy nature, but occasionally intermixed with earths of a lighter and more open sort. The writer of the account of the agriculture of the former of the above counties, states, that the weald part of that district was in ancient times an immense wood or forest, inhabited only by herds of deer and hogs, and belonged wholly to the king. That by degrees it became peopled, and interspersed with villages and towns; and by piece-meal, was, for the most part, cleared of its wood, and converted into tillage and pasture. There are, however,

however, some woodlands still in their original state; and by the author of that of the latter, it is remarked, that so predominant is the timber and wood of one sort or another in the weald of that county, that when viewed from any eminence in the neighbourhood, it presents to the eye hardly any other prospect but a mass of wood, which is, it is thought, to be ascribed to the great extent and quantity of wood, preserved by a custom of a nature so extraordinary, that it is not a little surprising no steps have been taken to put an end to it.

When this county was first improved by clearing, as in the other district, it was, it is said, a common practice to leave a *shaw* of wood several yards in width, to encompass each distinct inclosure, as a nursery for the timber and other plants. The sizes of these inclosures being small, they must of necessity contribute to render the general appearance of the tract woody.

Anterior to the Conquest, the weald of this county was, it is said, a continued forest, extending from the borders of the first district to the confines of Hampshire, across the whole of it; and the names of a variety of parishes situated in this line, and evidently derived from Saxon original, attest this fact to the present day. In short, the forest now remaining occupies, it is said, a considerable portion of the county.

The weald parts of both these counties were probably once one great forest.

It is noticed, that there is, perhaps, no object in the weald of the latter county, so worthy of attention and observation as the growth of timber; that there is no region of the earth where trees of all kinds thrive better, but especially those of the oak and ash sorts. The tract there distinguished by the title of the Weald has formerly, it is stated, been covered with trees, and it was called the forest of Anderida; and that now, even if a field be neglected, it will become a wood, principally of oak and birch, intermixed with hazel, some kinds of willow, and dog wood.

This disposition for the growth and raising of wood and timber should, in all cases of weald land where it cannot be converted to a better or more profitable purpose, be taken advantage of and promoted, by proper planting and encouraging the natural growth of the wood thrown up, as it may form one great feature in the improvement of such land, and be productive of vast benefit in bringing every portion and sort of it to the greatest profit.

WEALREAF, in our *Old Writers*, signifies the robbing of a dead man in his grave.

The word comes from the Saxon *weal*, *strages*, and *reaf*, *spoliatio*.

WEANEL, a country term for a young beast newly weaned, or taken from sucking its dam.

WEANING, ABLACTATION. See ABLACTATION.

WEANING *Young Live-Stock*, in *Rural Economy*, the separating them from the mothers in the different kinds, for different purposes, and in different intentions.

Foals, where they are designed for the saddle, should, on being taken from the mothers, be put into some safe sheds or other proper places at a distance, where they can be quiet and out of the hearing of the mares, being well supplied with the necessary sorts of food and good water for a day or two; the buildings should be connected with grass-fields, into which they can be turned in the day-time, but be always brought up for the night, for some time, having proper kinds of dry food then given them in full quantities, so as to get them on well at first. Some intelligent breeders have their young horse-stock fed, after weaning, with coarsely ground oats and one-third flour,

divided into proper feeds, and given on the nights in the houses. This, it is said, pushes them on early to a full growth, and that they never become stunted afterwards. In some instances, it may be useful and proper to put the colt and filly foals into separate pastures. Where a number are to be weaned at a time, it is of advantage to have the pasture-lands pretty large. See BREEDING, FOAL, and HORSE.

In the weaning* of the young of neat cattle, the business is accomplished at different times or ages of the animals, as the nature of the purpose for which they are designed may be; when for rearing as stock, it is often done immediately, or in a few days or weeks, and when for fattening, not at all. If for sale, the time is uncertain, depending on the demand. Where good neat cattle-stock is the object, as soon as the natural food milk is laid aside, a substitute of some good sort of diet should be had recourse to, such as oat or barley-meal, stirred in with the jelly of linseed, that has been produced by being steeped in hot water, and mixed with flat milk; which should be continued until they become capable of eating more firm and solid kinds of food, such as either oats, split beans, and chopped hay, or bran, and barley-flour mixed: in the early spring they should be turned out into good grass pastures in warm situations. By these means they will be brought on well, and become good strong stock. For the purpose of rearing, as well as that of the butcher, those that are dropped early are to be preferred, as after the early spring months, they are not found capable of gaining sufficient strength and hardness before the succeeding winter comes on, or a proper size and growth by the ensuing spring.

In the buying of the young of neat cattle for weaning there are many systems of management among farmers: some prefer bull calves for castration, and which they keep, in some cases, until they become reared, and are fat bullocks fit for the market; others buy cow-calves of the true short-horned, or some other good milking-breed, which they sell at two years, or two years and a half old, and upwards, to the cow-keepers as milking-stock. In this method, they are collected from the latter end of the summer through the autumn of the above true breed, as others will not do from Yorkshire, and other places where they are to be met with of the right kind, as such sell better, and more readily to the cow-keepers for affording milk. In weaning, they are then first put to skim-milk, and tempted as soon as possible to eat some other good food, as bran, oats, oil-cake, the sweetest hay, common turnips, and cole or rape; but nothing is found to do better for them than the Swedish turnip cut small. In keeping them, they should have great attention to cleanliness, and the proper and regular feeding of them. In this way they are continued, being kept in sheds in the night-time, and turned out by day, until the spring, when the ray-grass becomes ready, and then they may go out gradually altogether, according as the weather may be: after ray-grass to the best marshes or pastures; in the autumn to cole or rape that is feeding off for wheat, and after that to turnips: it is a rule with some to feed them through the whole period of keeping them as well as possible. This is expensive, but it is conceived, that if they will not pay for good keeping, they will not for bad. Some, however, when they are turned out, make them the followers of the fattening flock.

In this system there are those, too, who buy both cow and bull-calves, disposing of the former in the above manner, and keeping the latter raising a succession of steers for the grazing or fattening farmers.

All these modes, though hazardous in some instances, are often

often very beneficial. A man is required for the purpose, in autumn, winter, and spring, when the business is carried on upon a large scale. See CALF, BREEDING, and CATTLE. Also COW-KEEPING.

The weaning of lambs is a matter of some trouble and difficulty in many cases; it should be done towards the latter end of the summer, according to circumstances, but never be delayed too long, as the ewes may thereby be greatly hurt in different ways. After the lambs are taken, or lifted as it is sometimes called, from the mothers, they should be allowed to pass the night about the fold or place. In the following morning some of them will begin to eat, and teach the others to do the same. They should then be removed to some convenient soft grassy pasture, disturbing them as little as possible, care being taken that they do not waste or exhaust themselves by running. If there be any danger of their not resting quietly the first night after they are removed, it is said that it may be effectually prevented by pasturing them with their mothers the night immediately preceding their weaning, on their future pasture, and driving them to the fold or other place directly in that road or way by which the lambs are to be removed from it. In the course of ten or twelve days both the lambs and the ewes may be pastured together again without inconvenience. See LAMB and SHEEP.

Store swine should constantly be weaned at the end of a few weeks, as about six or eight, otherwise they do much injury to the sow. The young pigs should be well fed for some time afterwards, in order to push them on to their proper growth, and prevent their becoming dwarfish. The want of attention to this often produces a poor stunted sort of pigs, worth little or nothing. See SWINE.

WEANLING, a term applied in some districts to the newly-weaned calf. See WEANING.

WEAPONS. See ARM and ARMOUR.

WEAPON-Salve, a kind of unguent, supposed to cure wounds sympathetically, by being applied, not to the wound, but to the weapon that made it. See SYMPATHETIC Powder, and TRANSPLANTATION.

WEAR, or WEER, a great flank, or dam in a river; fitted for the taking of fish, or for conveying the stream to the mill. See FISHING, and WEIR.

WEAB, in Geography. See WERE.

WEARE, a township of America, in New Hampshire, in the county of Kellsborough, containing 2634 inhabitants; 18 miles S.W. of Concord.

WEARING, in Sea Language. See VEERING.

WEARY BAY, in Geography, a bay on the N.E. coast of New Holland, S. of Endeavour river.

WEASEL, WEESEL, Common, in Zoology, a species of the mustela. See MUSTELA *Vulgaris*.

The common weasel usually resides in cavities under the roots of trees, as well as of banks near rivulets, &c. from which it occasionally sallies out in search of birds, and more especially of field-mice, great multitudes of which it destroys.

In Norway, Sweden, Russia, and Siberia, the weasel always changes to white at the approach of winter. In Siberia it is called *lasmitka*; and the skins are sold to the Chinese for three or four rubles per hundred.

We have authentic accounts of this animal's being so completely tamed, as to exhibit every mark of attachment to its benefactors, and to be as familiar as a cat or lap-dog. A lady took one of these animals under her protection; and fed it from her hand with warm milk, and also with veal, beef, or mutton. When it is satisfied it generally goes to

sleep, and when it wakes, it amuses itself with various frolics, and bestows the most affectionate caresses on its guardian. It distinguishes the voice of its benefactors amidst twenty people, and gives her a decided preference to all the rest. Among other curious particulars which this lady has recited, we cannot forbear mentioning the curiosity of this animal; it being impossible, as she says, to open a drawer or a box, or even to look at a paper, which this little creature will not also examine. Aldrovandus indeed confirms the account given by Buffon; expressly asserting, that weasels are easily tamed, and that, when tame, they are remarkably playful; adding, at the same time from Curdan, that if their teeth are rubbed with garlick, they will not afterwards presume to bite. This writer also affirms, that the weasel sometimes carries her young in her mouth from place to place several times in a day, when she suspects that they will be stolen from her; resembling some other animals in this respect. For other species of weasel we refer to MUSTELA and VIVERRA; and we shall here add some few species, mentioned by Dr. Shaw, which have not been noticed under either of those articles. Such are the *Viverra Touan*, or ferruginous weasel, white beneath, with the tail naked towards the tip, the "Touan" of Buffon; a native of Cayenne, that lives in hollow trees, and feeds on worms and insects. The *V. Cuja*, or black weasel, with turned up snout, the "Cuja" of Molina, resembling the ferret in shape, manners, and teeth; a native of Chili, and preying upon mice. The *V. Maculata*, or dusky weasel, spotted with white; the "Spotted Martin" of governor Phillips, in its form somewhat resembling the fossane. There are also some other species, not yet sufficiently described, as the grey-headed weasel, or "La Grande Marte de Guiane," of Buffon; the South American weasel, or "La Fouine de la Guiane," of Buffon; the woolly weasel, or "La petite Fouine de la Guiane," of Buffon; the musky weasel of Pennant, a native of Bengal; and the slender-toed weasel with a bushy tail, described, as well as the other, by Mr. Pennant from a drawing; this latter being a native of Cochinchina.

WEASEL-Coot, in Ornithology, the red-headed mew, or *mergus minutus* of Linnæus.

WEATHER, in Agriculture, as denoting the state or disposition of the atmosphere, in regard to heat and cold, drought and moisture, fog, fair, or foul, wind, rain, hail, frost, snow, and other changes, is a sort of knowledge which is of vast utility and importance to the farmer, as the securing of his different produce in a perfect manner greatly depends upon it; and it is in and by means of the atmosphere, that plants are in some measure nourished, and that animals live and breathe: any alterations or changes in its heat, density, purity, or any other respect, must, of course, necessarily be attended with proportionable changes in the state of these.

The great but regular alterations which a little change of weather makes in many parts and sorts of inanimate matter, is fully and strikingly shewn in the common instances and cases of barometers, thermometers, hygrometers, and other such instruments; and it is owing partly to our inattention, and partly to other causes and circumstances, that we, like other animals, do not feel as great and as regular ones in the weight, pressure, and affections, in the tubes, chords, and fibres of our own bodies.

In order, however, fully to form and establish a proper and consistent theory or doctrine of the weather, it would be necessary to have accounts and registers of it regularly and carefully kept, in divers parts of the globe, for a long

series of years, whence, it is possible, we might be enabled to ascertain and determine the directions, breadths, and bounds of the winds, as well as other matters, and the nature of the weather they bring along with them; with the correspondence there may be between the weather of different places, in divers parts of the earth, and the difference between one fort and another at the same place; and thus, in time, learn to judge of, and foretell many great changes and emergencies; such as extraordinary heats, droughts, rains, frosts, snows, and some others. But hitherto very few, and only partial accounts in relation to the weather, have been, for the most part, kept. The general conclusions that have been drawn from the experiments that have been made, and the experience had upon this subject, are, that barometers generally rise and fall together, even at very distant places, and a consequent conformity and similarity of weather; and that this is the more uniformly so, as might be expected, as the places are the nearer together. That the variations of these instruments, too, are the greater, as the places are nearer to the pole; thus, for instance, the quicksilver in them at London, has a greater range by two or three lines than at Paris, and at that place a greater than at Zurich; and that at some places near the equator, there is scarcely any variation at all; that the rain in Switzerland and Italy is much greater in quantity, taking it for the whole year, than in the county of Essex, though the rains are yet more frequent, or there are more rainy days in that county, than in either of the other places; that cold contributes greatly to rain, and this apparently by condensing the suspended vapours, and thereby making them descend; thus, very cold months, or seasons, are very commonly followed immediately by very rainy ones, and cold summers are always wet ones; that high ridges of country, or mountains, such as the Alps and others, and the snows with which they are covered, not only affect the neighbouring places, but even distant countries, as these often partake of their effects; and the weather is mostly rainy in the vicinities of them, both in this and other countries.

The prognostics of the weather that are formed from other circumstances and observations are, that a thick dark sky lasting for some time, without either sun or rain, always becomes fair first and then foul; that is, it changes to a fair clear sky before it turns to rain. The reason is thought to be obviously this: the atmosphere is replete with vapours, which though sufficient to reflect and intercept the sun's rays from us, yet want density to descend, and while these vapours continue in the same state, the weather will do so too: accordingly such weather is commonly attended with moderate warmth, and with little or no wind to disturb the vapours, but having a heavy atmosphere to sustain them; the barometer being commonly high: but when the cold approaches, and by condensing the vapours, drives them into clouds, or drops, the way is made for the sun-beams to display themselves; until the same vapour, by farther condensation, be formed into rain, and fall down in drops. And that a change in the warmth of the weather is often followed by a change in the wind. Thus, the northerly and southerly winds, though commonly accounted the *causes* of cold and warm weather, are in reality the *effects* of the cold or warmth of the atmosphere; of which Dr. Derham assures us he has had so many confirmations, that he makes no doubt of the fact. Thus, it is common to observe a warm southerly wind, suddenly changed to the north, by the fall of snow or hail; or to see the wind in a cold frosty morning north, when the sun has well warmed the air, wheel towards the

south, and again turn northerly or easterly in the cold of the evening.

From the rules laid down by the shepherd of Banbury, many interesting and useful deductions may be made in regard to the weather: it may be concluded, that when the sun rises red and fiery, there will be wind and rain; but that when it rises cloudy, and the clouds soon disappear or lessen, there will certainly be fair weather; and that when the evening is red and the morning grey, a fine day may mostly be predicted.

That when there are small and round clouds, of a dapple grey colour, with a north wind, it may be determined, that there will be fair weather for two or three days; but that large clouds like rocks are a sign of great showers. And that when small clouds increase, it is an indication that there will be much rain; but that if the large clouds are seen to lessen, there will be fair weather. In summer or harvest, it may also be considered, when the wind has been south two or three days and it grows very hot, and clouds are seen to rise with great white tops like towers, as if one were on the top of another, being joined together with black on the lower side, a sign that there will be thunder and rain suddenly. And that when two such clouds rise, one on each hand, it is high time to make haste to shelter.

That when a cloud is seen to rise against the wind, or the side wind, it is a sure sign that when the cloud comes up near you, the wind will blow the way in which the cloud came. It is the same, too, with the motion of a clear place in the sky, when all the parts of it are thick except one edge. That, at all times, when the clouds look black in the west, it is sure to rain; or if raining, it is sure to continue, whatever quarter the wind may be in: and that, on the contrary, if it should break in the west, it is sure to be fair. That fair weather for a week, with a south wind, is likely to produce a great drought.

That the wind usually turns from north to south quietly, but comes back to north strong and with rain. That sudden rains never last long; but that when the air grows thick by degrees, and the sun, or moon and stars, shine dimmer and dimmer, it is likely to rain for some time.

That when it begins to rain from the south with a high wind for two or three hours, and then the wind falls but the rain continues, it is likely to rain twelve hours or more; and that it generally rains until a strong north wind clears the air. But that when it begins to rain an hour or two before sun rising, it is likely to be fair before noon, and to continue so that day; but that if the rain begin an hour or two after sun rising, it is likely to rain all that day, unless the rainbow be seen before it rains.

That when mists rise in low ground and soon disappear, it is a sign that there will be fair weather; but that when they rise to the hill tops, there will be rain in a day or two. That a general mist before the sun rises, when near the time of full moon, is a sign of fair weather. That when there are mists in the new moon, there will be rain in the old; and if there are mists in the old moon, there will be rain in the new. That in regard to the seasons, as spring and summer, when the last eighteen days of the month of February and the first ten days of the following month are for the most part rainy, the spring and summer may be concluded likely to be so too. It is said also, that a great drought has never been known by the writer, but which began at that time. In respect to the winter, when the end of October and the beginning of the following month are, for the most part, warm and rainy, the two beginning months of the new year are likely to be frosty and cold, except after a very

WEATHER.

dry summer. But that when October and the following month are snowy and frosty, the two beginning months of the new year may be likely to be open and mild.

Something may be drawn from the habits, cries, and course of animals, in respect to the weather. It is remarked, that in summer, when sheep rise early in the morning, it is a sure sign of either rain, or a very hot day; and that, in all seasons, when they jump and play much about, it is an indication of rain or wind, but generally of both, in the summer, and of very stormy weather in the winter. That in winter, when the sheep lie under a hedge, and seem loath to go off to pasture, and bleat much, it is considered a sign of a storm. And that, when sheep are fed with hay in the winter, and in frosty and snowy weather they leave the hay, it is a certain sign of the frosts breaking up.

That when rabbits get out to feed early in the morning, it is a sign of rain in the night in summer, and of either rain or snow in winter; and that when it is likely to be a bad night, they will be apt to get home before it is dark.

That pigs appear very uneasy before high winds, and run about squeaking as if they were in great pain.

That when owls screech, it is a certain sign of rain, and mostly in a very short time. Also, that when wood-peckers cry, it is a sign of rain. For this reason, they are called, in some places, rain-fowl. That likewise, when peacocks cry much, it is a sign of rain. That when the cocks begin to crow while it rains, it is a sign of fair weather.

That before a wet summer, the swans build their nests very high; but that before a dry summer they build very low. That the bittern or bitter bump does the same. But that when the raven is observed early in the morning soaring round and round at a great height in the air, it is a sure sign the day will be fine, and that the weather is likely to set in for fair. And that in summer when the bat is seen flying and flitting about very late in the evening, the next day is likely to be fair. That likewise when the swallow is observed to fly high, the weather will most likely be warm and fair. But that when it is noticed to fly low, and dip the tips of its wings in the water as it skims over the surface, the weather is likely to be rainy. And that the continued squalling of the guineez-fowl, and the quacking of ducks and geese, are certain signs of rain.

That before great storms the missel thrush sings particularly loud, and continues to do so until the rain begins. On this account, in some places, it is called the storm-fowl. Also, that in autumn, when flocks of wild geese are seen flying over in a westerly direction, it is a sign there soon will be hard weather. That the early appearance of the wood-cock and field-fare likewise indicate cold hard winters.

That when in the time of hay-making the black snails are to be seen stretched along on the swath of grass, it is a sign of rain. That when frogs look black instead of a golden yellow colour, it is a sign of rain. And the loud hoarse croakings of frogs are sure signs of rain.

That in autumn, when the dor beetle is seen flying about in the evening, the next day is likely to be fine. Also, that when bees do not go out as usual, but keep in their hives, it is a sign of rain. Much information of this nature may be found in Marshall's "Minutes of the Southern Counties," which may be consulted by the cautious farmer with great utility and advantage, in regard to the weather he may have for securing his produce in different cases.

There are other conclusions, too, in respect to the weather, that may be drawn from plants of different kinds, as most vegetables expand their flowers and down in sun-shiny weather; and towards the evening and against rain close them up, especially at the beginning of their flowering,

when the seeds are sensible and tender. This is visible and evident enough in the down of dandelion, and many other downs, and eminently so in the flowers of pimpernel; the opening and shutting of which make what is termed the countryman's *weather-wifer*, by which he foretels the weather of the following day. The rule is, when the flowers are close shut up, it betokens rain and foul weather; but when they are open and abroad fair weather. And lord Bacon observes, that the stalks of trefoil swell against rain, and grow more upright; and that the like may be noticed, though less sensibly, in the stalks of most other plants. It is added, too, that in the stubble fields there is found a small red flower, called by the country people pimpernel, which opening in a morning is a sure indication of a fine day.

"Est & alia (arbor in Tylis) fimilis, foliosior tamen, roseique floris; quem noctu comprimens, aperire incipit folis exortu, meridie expandit. Incolæ dormire eum dicunt. Plin. Nat. Hist. lib. xii. c. 11. See *Sleep of PLANTS*, and *VIGILÆ Florum*.

It is readily conceivable that vegetables should be affected by the same causes as the weather, as they may be considered as so many hygrometers and thermometers, consisting of an infinite number of *tracheæ* or air-vessels, by which they have an immediate communication with the air or atmosphere, and partake of its moisture, heat, and other changes. And hence, too, it is, that all wood, even the hardest and most solid, swells in moist weather, the humid vapours easily insinuating themselves into the pores of it, especially of the lighter and drier kinds, from which they become applicable to many purposes of art, and may tend to shew the change of the weather in some instances.

Hence we derive a very extraordinary use of wood, *viz.* for breaking rocks for mill-stones.

The method at the quarries is this:—Having cut a rock into a cylinder, they divide that into several less cylinders, by making holes at proper distances round the great one; the holes they fill with so many pieces of fallow wood, dried in an oven, which, in moist weather, becoming impregnated with the humid corpuscles of the air, swell; and, like wedges, break or cleave the rock into several stones.

The attentive farmer should store up in his mind as many of the useful rules relating to the weather as possible, as they may serve him very effectually, on many occasions, in the performance of his various business. See *ATMOSPHERE*, *METEOROLOGY*, *HEAT*, *RAIN*, *WIND*, &c.

The members of our Royal Society, the French Academy of Sciences, and many authors of note, have made considerable essays this way; and the practice of keeping meteorological journals has, of late years, become very general. For instructions and examples pertaining to this subject, see Phil. Transf. vol. lxxv. part ii. art. 16.

Eras. Bartholin has observations of the weather for every day throughout the year 1671. Mr. W. Merle made the like at Oxford, for seven years, with a very remarkable care and accuracy. Dr. Plott did the same at the same place, for the year 1684. Mr. Hillier, at Cape Corfe, for the years 1686, 1687. Mr. Hunt, &c. at Gresham college, for the years 1695, 1696. Dr. Derham, at Upminster in Essex, for the years 1691, 1692, 1697, 1698, 1699, 1703, 1704, 1705. Mr. Townley, in Lancashire, in 1697, 1698. Mr. Cunningham, at Emin in China, for the years 1698, 1699, 1700, 1701. Mr. Locke, at Oats in Essex, 1692. Dr. Scheuchzer, at Zurich, in 1708; and Dr. Tilly, at Pifa, the same year. See the Phil. Transactions.

The form of Dr. Derham's observations we give as a specimen of a journal of this kind; observing that he notes

WEATHER.

the strength of the winds, by 0, 1, 2, 3, &c. and the quantity of rain, as it fell through a tunnel, in pounds and centefimals.

Phenomena of the Weather, October 1697.

Day.	Hour.	Weather.	Wind.	Barometer.	Rain.
27	7	Fair.	S.W. 2	29 37	1 52
	12	Rain.	S.W. by W. 5	29 34	
	9	Stormy.	0	29 88	0 29

We have several schemes for keeping meteorological journals or diaries of the weather, extant in the Philosophical Transactions, the Medical Effays of Edinburgh, and in other books. The Ephemerides Ultrajectinæ may also be consulted. The instruments requisite for such journal are, a *Barometer*, *Thermometer*, *Anemoscope*, and *Ombrometer*, which see in their proper places. See a Collection of ingenious observations, and meteorological conjectures, by Dr. Franklin, in his Experiments, &c. p. 182, &c. See EVAPORATION, RAIN, and WIND.

We shall here specify some of the common indications of changes of weather that may be observed at sea. Under the article TIDES we have already stated, that they are raised by the joint actions of the sun and moon; the spring-tides being raised by the sun, and the neap-tides by the difference of the actions of these bodies; and, also, that the spring-tides, near the time of an equinox, are higher than at other times of the year. Now, since the atmosphere is a fluid much lighter than water, it must, therefore, be more affected about the times of new and full moon, and in the months of March and September, than at other times. This is confirmed by observation; for, about the times of new and full moon, an alteration in the state of the weather usually happens; and the violent gales about the time of the equinoxes, called *equinoxial gales*, are well known, and expected by every seaman.

According as the state of the atmosphere is more or less disturbed, it is evident the appearance of the heavenly bodies will be more or less altered. Thus, if the moon appears paler than usual, or if there is a halo about the moon, rain will probably follow soon after. Several circles about the moon portend wind. These observations are also applicable to the sun. If the moon appears of a red colour, or if the moon's horns are blunt, they are signs of wind, which may be expected from that quarter to which the bluntest horn is directed. In viewing the moon with a telescope in a quiet evening, if one part of the moon's limb be observed to be tremulous, while the opposite part of the limb is without the least apparent tremor, the wind may be expected from that point to which the limb free of tremors is directed. A red circle about the moon towards the time of full moon indicates wind.

One of the best known signs in the heavens is the *Rain-bow*; which see. When the blue and yellow parts of the rainbow are very bright, or if all of it vanish at the same time, it will be fair weather: if the bow appears to be broken in several places, tempestuous weather may be expected.

From the various appearances of the clouds, (see CLOUD,) which are vapours floating in the atmosphere, producing rain, hail, snow, thunder, and lightning, the approaching weather may, in some measure, be predicted. The height of the clouds seldom exceeds a mile; and the summits of high mountains are free of clouds.

When the sky is of a fine blue colour, without any clouds,

it will continue to be fair weather; but if it is of a very dark blue, clouds will be formed, and rain, wind, or fog, will soon follow.

When the sky appears very much clouded for some time, without rain, it generally first clears up, and then changes to rain. This is accounted for as follows:—The atmosphere at that time being replete with vapours, which, though sufficient to intercept the rays of the sun, yet want density to descend; and while the vapours continue in the same state, the weather will do so too; and such weather is commonly attended with moderate warmth, and with little or no wind to disturb the vapours, and an heavy atmosphere to support them, the barometer being commonly high. But when the cold approacheth, and, by condensing the vapours, drives them into clouds or drops, then way is made for the sun-beams, till the same vapours, by farther condensation, be formed into rain, and fall down in drops.

If the clouds, in a summer evening, gradually diminish, and at last vanish, it will be fine weather; but, if they increase, and small clouds be observed to move very swiftly underneath, it will be rain soon after; or, if the clouds change to a dark colour, thunder may be expected.

If the clouds in the western hemisphere, at the time of sun-set, are tinged with a light red and yellow; or, if there are no clouds, and the sky, towards that part of the horizon where the sun sets, be of a beautiful red and yellow, it will be fine weather: but if the sun be of a pale colour, or if the clouds change to a dark red, and continue, it will be rain. The clouds tinged with a dark red in the opposite hemisphere to the sun, whether at rising or setting, presage wind.

In winter, when large clouds are observed with white edges, and a strong blue sky above them, it will be hail or snow; or probably these may be dissolved into rain before they reach the earth.

When there are two or more strata of clouds moving in different directions, rain generally follows. Many small clouds pretty high, and other appearing at the same time in form of fleeces of wool, denote wind.

A cloud of an oblong form, sometimes called *Noah's Ark*, seen in a clear sky, and changing from a fine light to a dark colour, is a sign of rain; but, if it changes from dark to light, it is a sign of fair weather.

A small black cloud seen in a clear sky, or several small clouds collecting near each other, are an indication of wind from the quarter from whence they are observed to move: also, if the clouds are observed to diverge from a point in the horizon, wind may be expected from that, or from the opposite point.

When stars of the second and third magnitudes are suddenly obscured, wind or rain will soon follow. Those meteors, commonly called *falling* or *shooting* stars, are usually the forerunners of wind.

That appearance in the heavens resembling a portion of the rainbow, but apparently broader than any part of the arch when complete, and generally known by the name of a *Wind-gall*, is an indication of an approaching gale.

The *Aurora Borealis*, (which see,) or northern light, is a sign of wind from between the S. and S.W. points, attended with hazy weather, and small rain, the gale generally commencing between twenty-four and thirty hours after the first appearance of the aurora. The violence of the gale, and the time of its commencement after the aurora borealis is seen, and duration, depend, in a great measure, upon the brightness and motion of the aurora; for the more brilliant the aurora, and the quicker its motions, the gale will happen sooner, be more violent, and of shorter duration.

A change

A change in the wind commonly produces a change in the weather. Thus, in fair weather, if the wind changes to the opposite point, rain may be expected: but, in rainy or foggy weather, it will clear up soon after the change of the wind.

In a storm at sea, a fiery meteor, in form of a ball, affording an obscure flame like a candle burning faintly, is sometimes seen adhering to the masts, yards, &c. or leaping from one part to another. When only one is seen, it is called *Helena*, and is a sign that the severest part of the storm is yet to come. When two are observed, they are called *Castor* and *Pallux*, and sometimes *Tyndarida*, and denote the storm to be near an end. If five of these balls are seen together, which the Portuguese call the *Virgin Mary's Crown*, it is considered to be a sure sign that the storm will be soon over. When the meteor adheres to the masts, yards, &c. it is concluded, from the air not having sufficient motion to dissipate the flame, that a calm will soon ensue; but if it leaps from one place to another, that it denotes a storm.

At the Cape of Good Hope, an approaching storm, or gale of wind, is easily known by the following observations:—When a small black cloud, called the *Ox-eye*, is observed to rise from the top of Table Mountain, which continues to increase until the heavens be almost entirely overclouded, the storm then commences. A similar phenomenon usually precedes a storm at the Arabian gulf: this storm comes from the north, and is accompanied with a great quantity of red sand.

When a hurricane happens in the West Indies, it is generally either at new or full moon, or at the quarters, and the signs are as follow:—The sun and moon appear redder than usual, and are sometimes surrounded with a halo; the stars at night appear larger and fainter; the sky in the N.W. quarter is dark; the hills are clear of those clouds and mists which usually hover about them; the sea emits a strong smell, and is violently agitated, often when there is no wind; the wind also veers about to the west, from whence it sometimes blows with intermissions violently and irregularly for about two hours at a time.

The tumbling of porpoises indicates a gale of wind. When a swell sets from any particular point, there being no wind, a gale may be soon expected from that point.

From a very great number of meteorological observations, made in England between the years 1677 and 1789, Mr. Kirwan has deduced the following probable conjectures of the weather:

1. That when there has been no storm before or after the vernal equinox, the ensuing summer is generally *dry*, at least five times in six.
2. That when a storm happens from any easterly point, either on the 19th, 20th, or 21st of March, the succeeding summer is generally *dry*, four times in five.
3. That when a storm arises on the 25th, 26th, or 27th of March, and not before, in any point, the succeeding summer is generally *dry*, four times in five.
4. If there be a storm at S.W. or W.S.W. on the 19th, 20th, 21st, or 22d of March, the succeeding summer is generally *wet*, four times in five.

We shall further subjoin the following observations:

1. A moist autumn, with a mild winter, is generally followed by a cold and dry spring, which greatly retards vegetation.
2. If the summer be remarkably rainy, it is probable that the ensuing winter will be severe; for the unusual evaporation will have carried off the heat of the earth. Wet summers are generally attended with an unusual quantity of

feed on the white thorn and dog-rose bushes. Hence, the unusual fruitfulness of these shrubs is a sign of a severe winter.

3. The appearance of cranes, and birds of passage, early in autumn, announces a very severe winter; for it is a sign that it has already begun in the northern countries.

4. When it rains plentifully in May, it will rain but little in September, and *vice versa*.

5. When the wind is S.W. during summer or autumn, and the temperature of the air unusually cold for the season, both to the feeling and the thermometer, with a low barometer, much rain is to be expected.

6. Violent temperatures, as storms or great rains, produce a sort of crisis in the atmosphere, which produces a constant temperature, good or bad, for some months.

7. A rainy winter predicts a sterile year; a severe autumn announces a windy winter.

For indications of the weather by the barometer, see BAROMETER. By the *Thermometer*, (which see,) Mr. Dalton deduces the following conclusions:

The mean altitude of the mercury in the thermometer in Britain is about 55° : if higher, the weather is warm; but if lower, it is cold.

A quick and considerable alteration in the altitude of the mercury in the thermometer indicates rain.

If it begins to snow when the thermometer is below 32° , the mercury generally rises to that altitude, and continues while the snow falls. If the weather clears up soon after, a severe cold may be expected. See also HYGROMETER, from which it is inferred, that, when the index of the hygrometer points to *dry*, and continues proceeding towards extreme dryness, fair weather, and probably wind, may be expected; but if the index returns to the mean state, it will be rain. If the index points to *moist and increasing*, rain will soon follow; if it returns towards the mean, it will be fair weather.

As to the supposed influence of the moon upon the weather, see *Influence of the Moon*.

WEATHER, in *Sea Language*, is used as an adjective, and applied by mariners to every thing lying to windward of a particular situation: thus, a ship is said to have the weather-gage of another, when she is farther to windward. Thus also, when a ship under sail presents either of her sides to the wind, it is then called the weather-side, or weather-board; and all the rigging and furniture situated on it are distinguished by the same epithet; as the weather-shrouds, the weather-lifts, the weather-braces, &c.

To WEATHER, is to sail to windward of some ship, bank, or head-land.

WEATHER-Beaten. Scattered by a storm.

WEATHER-Bit, denotes a turn of the cable of a ship about the end of the windlafs, without the knight-heads. It is used to check the cable, in order to slacken it gradually out of the ship, in tempestuous weather, or when the ship rides in a strong current. See RING-Ropes.

WEATHER-Boarding, among *Carpenters*, &c. denotes the nailing up of boards against a wall, and sometimes the boards themselves when thus nailed up.

WEATHER-Cock, or *Weather-Vane*, a moveable vane, in form of a cock, or of other shape, placed on high, to be turned round according to the direction of the wind, and point out what quarter the wind blows from. See VANE.

WEATHER-Cord. See HYGROMETER.

WEATHER, *Hard-a*. See HARD.

WEATHER-House. See HYGROMETER.

WEATHER-Gage, in *Sea Language*. When a ship or fleet is to windward of another, she is said to have the weather-gage of her.

WEATHER-Glasses are instruments contrived to indicate the state or disposition of the atmosphere, as to heat, cold, gravity, moisture, &c. to measure the changes befalling it in those respects; and by those means to predict the alteration of weather, as rains, winds, snow, &c.

Under the class of weather-glasses, are comprehended *barometers, thermometers, hygrometers, manometers, and anemometers*, of each of which there are divers kinds. See their theories, constructions, uses, kinds, &c. under **BAROMETER, THERMOMETER, HYGROMETER, &c.**

WEATHER-Quarter, in *Sea Language*, that quarter of the ship which is on the windward side.

WEATHER-Quoil or *Coile*, is the turning of the ship's head about, so as to lie that way which her stern did before without loosing any sail, but only by bearing up the helm.

WEATHER-Side, the side of a ship upon which the wind blows.

WEATHER-Shore, a name given to the shore lying to windward.

WEATHER-Tiling, in *Building*, the covering of the upright side of a house with tiles.

WEATHERER, in *Geography*, one of the smaller Shetland islands. N. lat. 60° 35'. W. long. 1° 13'.

WEATHERING, a doubling, or failing by a point, or place.

WEATHERING, among *Mill-wrights*. See **WIND-Mill**.

The WEATHERING of a Hawk, among *Falconers*, is the setting of her abroad to take the air.

WEATHERSFIELD, in *Geography*, a town of the state of Connecticut, in the county of Hartford, founded about the year 1639, containing 2868 inhabitants; 5 miles S. of Hartford.—Also, a township of Vermont, in the county of Windfor, containing 2115 inhabitants; 3 miles S. of Windfor.—Also, a town of Ohio, in the county of Trumbull, containing 232 inhabitants.

WEAVER, in *Manufactures*, one who practises the art of weaving.

Persons using the trade of a weaver, shall not keep a tucking or fulling-mill, or use dyeing, &c. or have above two looms in a house in any corporation or market-town, on pain of forfeiting 20s. a week: and shall serve an apprenticeship for seven years to a weaver or clothier, or shall shall forfeit 20l. &c. 2 & 3 Ph. & M.

WEAVER's Alarm. This contrivance is only a weight fastened to a packthread, which is placed horizontally, so that in a certain time a candle may burn down to it. Then the flame of the candle setting fire to the thread, the weight falls, and awakens the sleeping person. See *Phil. Trans.* No. 477. sect. 14, where we have a figure to explain the invention, which has got its name from being in frequent use among the weavers.

WEAVER's Lake, in *Geography*, a lake of New York; 3 miles N.W. of Otsego lake.

WEAVING, in *Manufactures*, is the art of combining and uniting threads together, to form cloth. *Stocking-knitting* or weaving is a distinct art from cloth-weaving, the manner of combining the thread, being essentially different in the two. In the stocking fabric, the whole piece consists of one continuous thread, which is formed into a series of loops in successive rows; and the loops of each row are drawn through the loops of a former row. See **STOCKING-Frame**.

Woven cloth is always composed of two distinct systems

of threads, called the warp and the weft: these traverse the piece of cloth in opposite directions, and are usually at right angles to each other. Those threads, (or, as the weavers call them, yarns,) which run in the direction of the length of the web or piece of cloth, are called the warp, and they extend entirely from one end of the piece to the other. The cross thread, or yarn, runs across the cloth, and is called the woof or weft. This is in fact one continued thread through the whole piece of cloth, being woven alternately over and under each yarn of the warp, which it crosses, until it arrives at the outside one. It then passes round that yarn, and returns back over and under each thread, as before; but in such a manner, that it now goes over those yarns which it passed under before, and *vice versa*; thus firmly knitting or weaving the warp together. The outside yarn of the warp, round which the woof is doubled, is called the selvage, and cannot be unravelled without breaking the weft. The strength of the cloth, in the direction of the length, must depend on the threads of the warp; but its strength in the opposite direction will depend upon the weft; and the strength of these two threads should be always properly proportioned to each other.

The combined arts of spinning and weaving are among the first essentials of civilized society, and we find both to be of very ancient origin. The fabulous story of Penelope's web, and, still more, the frequent allusions to this art in the sacred writings, tend to shew, that the fabrication of cloth from threads, hair, &c. is a very ancient invention. It has, however, like other useful arts, undergone a vast succession of improvements, both as to the preparation of the materials of which cloth is made, and the apparatus necessary in its construction, as well as in the particular modes of operation by the artist. Weaving, when reduced to its original principle, is nothing more than the interlacing of the weft or cross threads into the parallel threads of the warp, so as to tie them together, and form a web or piece of cloth. This art is doubtless more ancient than that of spinning, and the first cloth was what we now call matting, *i. e.* made by weaving together the shreds of the bark, or fibrous parts of plants, or the stalks, such as rushes and straws.

This is still the substitute for cloth amongst most rude and savage nations. When they have advanced a step farther in civilization than the state of hunters, the skins of animals become scarce, and they require some more artificial substance for clothing, and which they can procure in greater quantities. Nevertheless, some people are still ignorant of the art of weaving; for the cloth made in the islands of the South sea appears to be made by cementing or glueing the shreds together, rather than by weaving. From the description given by captain Cook, and other circumnavigators, and from the specimens which have been brought to Europe, their cloth, or rather matting, is in general produced by cohesion of the parts, rather than texture. This assimilates it more to the ideas which we attach to paper, or pasteboard, than to those which we form of cloth.

When it was discovered that the delicate and short fibres, which animals and vegetables afford, could be so firmly united together by twisting, as to form threads of any required length and strength, the weaving art was placed on a permanent foundation. By the process of spinning, which was very simple in the origin, the weaver is furnished with threads far superior to any natural vegetable fibres in lightness, strength, and flexibility; and he has only to combine them together in the most advantageous manner.

The art of weaving cloth has been so extensively applied

WEAVING.

in almost every civilized country, and the knowledge of its various branches has been derived from such a variety of sources, that no one person can ever be practically employed in all its branches; and though every part bears a strong analogy to the rest, yet a minute knowledge of each of these parts can only be acquired by experience and reflection. We will endeavour to give the reader as comprehensive an idea of the history and progress of this ancient and invaluable art as the nature of the thing, and the limits to which we are necessarily confined, will permit.

The history of this art is very little known, and its great antiquity necessarily involves the earlier eras of it in the most perfect obscurity.

The art of making linen, which was probably the first species of cloth invented, was communicated by the Egyptians, the inhabitants of Palestine, and other eastern nations, to the Europeans. By slow degrees it found its way into Italy; and it afterwards prevailed in Spain, Gaul, Germany, and Britain. The Belgæ manufactured linen on the continent; and when they afterwards settled in this island, it is probable they continued the practice, and taught it to the people among whom they resided.

When it is considered that the wants of mankind are nearly the same in all countries, it is not improbable that the same arts, however varied in their operations, may have been separately invented in different countries. It is not, however, certain that the art of making cloth is one which the Britons invented for themselves.

It is most probable that the Gauls learned it from the Greeks, and communicated the knowledge of it to the people of Britain. It is very certain that the inhabitants of the southern parts of Britain were well acquainted with the arts of dressing, spinning, and weaving, both flax and wool, when they were invaded by the Romans. Nevertheless, we have the authority of Julius Cæsar, that when he invaded Britain, the art of weaving was totally unknown to the Britons.

Whatever knowledge the Britons might possess of the clothing arts, prior to the invasion, it is very certain that these arts were much improved amongst them after that event. It appears from the *Notitia Imperii*, that there was an imperial manufactory of woollen and linen cloth, for the use of the Roman army then in Britain, established at *Venta Belgarum*, now called Winchester.

Many public acts relative to the woollen manufacture, in the earlier period of English history, evidently prove that the greater part of our wool was, for a very long series of years, exported in a raw state, and manufactured upon the continent.

In bishop Aldhelm's book concerning "Virginity," written about A.D. 680, it is remarked, "that chastity alone forms not a perfect character, but requires to be accompanied and beautified by other virtues." This observation is illustrated by the following simile, borrowed from the art of figure-weaving: "It is not a web of one uniform colour and texture, without any variety of figures, that pleaseth the eye, and appeareth beautiful; but one that is woven by shuttles, filled with threads of purple, and many other colours, flying from side to side, and forming a variety of figures and images, in different compartments, with admirable art."

Perhaps the most curious specimen of this ancient figure-weaving and embroidery, now to be found, is that preserved in the cathedral of Bayeux. It is a piece of linen, about 19 inches in breadth, and 67 yards in length, and contains the history of the Conquest of England by William

of Normandy; beginning with Harold's embassy, A.D. 1065, and ending with his death at the battle of Hastings, A.D. 1066. This curious work is supposed to have been executed by Matilda, wife to William, duke of Normandy, afterwards king of England, and the ladies of her court. Although it is certain that the art of figure-weaving was then known in Britain, it must be owned, that the piece of tapestry just mentioned owes most of its beauty to the exquisite needle-work with which it is adorned.

The silk manufacture was first practised in China, and the cotton in India. Both the woollen and linen were borrowed by the English from the continent of Europe; and for many ages, all the improvements in them in this country were first introduced into this country by foreign artificers, who settled amongst us.

About the close of the eleventh century, the clothing arts had acquired a considerable degree of improvement in this island. About that time, the weavers in all the great towns were formed into guilds or corporations, and had various privileges bestowed upon them by royal charters.

In the reign of Richard I., the woollen manufacture became the subject of legislation; and a law was made, A.D. 1197, for regulating the fabrication and sale of cloth.

The number of weavers, however, was comparatively small, until the policy of the wise and liberal Edward III. encouraged the art, by the most advantageous offers of reward and encouragement to foreign cloth-workers and weavers, who would come and settle in England. In the year 1331, two weavers came from Brabant, and settled at York.

The superior skill and dexterity of these men, who communicated their knowledge to others, soon manifested itself in the improvement and spread of the art of weaving in this island.

Many Flemish weavers were driven from their native country, by the cruel persecutions of the duke d'Alva, in the year 1567. They settled in different parts of England, and introduced or promoted the manufacture of baizes, serges, crapes, and other woollen stuffs.

About the year 1686, nearly 50,000 manufacturers, of various descriptions, took refuge in Britain, in consequence of the revocation of the edict of Nantz, and other acts of religious persecution committed by Louis XIV. These improvements chiefly related to silk-weaving.

The arts of spinning, throwing, and weaving silk, were brought into England about the middle of the 15th century, and were practised by a company of women in London, called silk-women. About A. D. 1480, men began to engage in the silk manufacture, and the art of silk-weaving in England soon arrived at very great perfection. See **SILK**.

The civil dissensions which followed this period, retarded the progress of these arts; but afterwards, when the nation was at rest, the arts of peace, and among others that of weaving, made rapid advances in almost every part of the kingdom.

In the latter part of the last century, the invaluable inventions of sir Richard Arkwright, introduced the very extensive manufacture of cotton, and added a lucrative and elegant branch of traffic to the commerce of Britain. The light and fanciful department of the cotton manufacture has become, in some measure, the staple manufacture of Scotland, whilst the more substantial and durable cotton fabrics have given to England a manufacture inferior, in importance and extent, only to the woollen trade.

At the present day, our superiority in point of quality is

WEAVING.

is universally acknowledged in the cotton manufacture ; but in those of silk, linen, and woollen, it is still disputed by other countries.

Loom.—Weaving is performed by the aid of a machine called a loom. The common loom for plain cloth is a very simple machine ; but some of the varieties which are used for weaving ornamental and figured cloth are very curious : still there are parts common to all. The principal of these are as follows.

1. The yarn-beam, which is a round wooden roller, on which is wound or rolled the warp, or yarns that are to form the length of the piece of cloth.
2. The cloth-beam is a similar roller, on which the cloth is rolled up when woven. The yarns of the warp are extended in parallel lines, between the yarn-roll and the cloth-roll, so as to form a horizontal plane, or sheet, and are combined together by the cross-threads, or weft.
3. The shuttle, which has a hollow to contain a bobbin or pirn of the weft.
4. The heddles, which are threads with loops or eyes, through which the yarns of the warp pass : the heddles are connected with the treadles, upon which the weaver places his feet, to draw down one set of heddles and raise up another, so as to open and separate the warp into two divisions, and allow a passage, called the shed, for the shuttle between them.
5. The reed, which is a frame containing a row of parallel shreds of reeds or cane, and the yarns of the warp pass between them, as it were between the teeth of a comb.
6. The reed is fixed in a frame, called the lay or lathe, which swings upon centres of motion. The use of the reed and lay is to comb or push the threads of the weft close to each other, and make the cloth close and dense.

The operation of weaving or working the loom for plain cloth consists of three very simple movements, *viz.* 1. Opening the shed in the warp alternately, by pressing the two treadles with his feet in opposite directions. 2. Driving or throwing the shuttle through the shed when opened. This is performed by the right-hand, when the fly-shuttle is used, and by the right and left alternately, in the common operation, wherein the shuttle is thrown from one hand and caught in the other. 3. Pulling forward the lay or batten to strike home the woof, and again pushing it back nearly to the heddles. This is done by the left-hand with the fly-shuttle, or by each hand successively in the old way.

There are several different ways of setting up a loom for weaving plain cloth ; but the principal parts are always made the same. We shall first describe that which is used for weaving plain silks : it is shewn in perspective in *Plate II. Weaving.* In this *A* is the yarn-roll or beam, on which the thread to form the warp is regularly wound ; *B*, the cloth-beam, or breast-roll, on which the finished cloth is wound up ; *D E*, the treadles, on which the weaver presses his feet ; *dd, ee*, are the heddles, or harness. These are each composed of two small rods *dd* and *ee*, connected together by several threads, forming a system of threads, which is called a heddle ; *ee* is another heddle, behind the former. In the middle of each thread of the heddle is a loop, through which a yarn of the warp is passed, every other yarn going through the loops of the heddle *ee*, and the intermediate yarns passing between the threads of that heddle, and afterwards through the eyes or loops of the other heddle *dd*.

The two heddles, *dd* and *ee*, are connected together by two small cords going over pulleys, suspended from the top of the loom, so that when one heddle is drawn down, the other will be raised up. The heddles receive their

motion from the levers or treadles *D E*, moved by the weaver's feet. The yarns of the warp being passed alternately through the loops of the two heddles, by pressing down one treadle, as *E*, all the yarns belonging to the heddle *ee* are drawn down ; and by means of the cords and pulleys, the other heddle *dd*, with all the yarns belonging to it, are raised up ; leaving a space, called the shed, of about two inches between the yarns, for the passage of the shuttle.

F, G G, H, (*fig. 2.*) is a frame, called the batten or lay, suspended by the bar *F*, from the upper rails of the loom, so that it can swing backwards and forwards, as on a centre of motion ; the bottom bar *H* is much broader than the rails *G G*, and projects before the plane about an inch and a half, forming a shelf, called the shuttle-race. The ends of the shuttle-race *H* have boards nailed on each side, to form two short troughs or boxes *I I*, in which pieces of wood or thick leather *kk*, called peckers or drivers, traverse. The peckers are guided by two small wires, fixed at one end to the uprights *G G*, and at the other to the end-pieces of the troughs *I I*. Each pecker has a string fastened to it, tied to the handle *y*, which the weaver holds in his right-hand when at work, and with which he pulls, or rather snatches, each pecker either to the right or left alternately.

R is the reed : it is a small frame, fixed upon a shuttle-race *H*, containing a number of small pieces of split reeds or canes ; or else of pieces of flat wire, of steel or brass ; but the cane is most common, although the frame is called the reed. When *fig. 2.* is in its place in the loom, the yarns of the warp pass between the canes or dents of the reed. In *fig. 2.* the reed is represented without the top or piece which covers it, and which is called the lay-cap. It is a rail of wood with a longitudinal groove along its lowermost side, for the purpose of sustaining the upper edge of the reed. The lay-cap is that part of the machine on the middle of which the weaver lays hold with his left-hand when in the act of weaving.

The shuttle (*see Plate I.*) is a small piece of wood pointed at each end, from three to six inches long. It has an oblong mortise in it, containing a small bobbin or pirn, on which is wound the yarn which is to form the weft ; and the end of this yarn runs through a small hole in the shuttle, called the eye. The shuttle has two little wheels on the under side, by which it runs easily upon the shuttle-race *H*.

Operation.—The weaver sits on the seat *M*, (*fig. 1.*) which hangs by pivots at its ends, that it may adapt itself to the ease of the weaver when he sits upon it. It is lifted out when the weaver gets into the loom, and he puts it in again after him. He leans lightly against the cloth-roll *B*, and places his feet upon the treadles *D E*. In his right-hand he holds the handle *y* (*fig. 2.*), and by his left he lays hold of the rail, called the lay-cap, which crosses the batten or lay *G G*, and serves to support the upper edge of the reed *R*. He commences the operations by pressing down one of the treadles with his foot : this depresses one-half of the yarns of the warp, and raises the other, as before-described. The shuttle is previously placed in one of the troughs *I*, against the pecker *K*, belonging to that trough. By the handle of the pecker, with a sudden jerk, he drives the pecker against the shuttle, so as to throw it across the warp upon the shuttle-race, into the other trough *I*, leaving the yarn of the weft, which was wound on the bobbin after it, in the space between the divided yarns. With his left-hand he pulls the lay towards him ; and, by means of the reed, the yarn of the weft, which before was lying loose between the warp, is driven up towards

WEAVING.

the cloth-roll: the weaver now presses down his other foot, which reverses the operation, pulling down the heddle which was up before, and raising that which before was depressed. By the other pecker he then throws the shuttle back again, leaving the woof after it between the yarns of the warp; and, by drawing up the batten, beats it close up to the thread before thrown.

In this manner the operation is continued until a few inches are woven; it is then wound upon the cloth-roll, by putting a short lever into a hole made in the roll, and turning it round, a click acting in the teeth of a ferrated wheel, prevents the return of the roll. At each end of the yarn-roll A, (*fig. 1.*) a cord is tied to the frame of the loom; the other ends of the cords have weights hanging to them. The rope causes a friction, which prevents the roll from turning (unless the yarn is drawn by the cloth-beam), and always preserves a proper degree of tension in the yarn.

T T (*fig. 1.*) are two smooth sticks (cotton-weavers have usually three) put between the yarns, to preserve the lease, and keep the threads or yarns from entangling.

In cotton-weaving these sticks or rods are kept at an uniform distance from the heddles, either by tying them together, or by a small cord with a hook at one end, which lays hold of the front rod, and a weight at the other, which hang over the yarn-beam.

The cloth is kept extended during the operation of weaving, by means of two hard pieces of wood, called a templet, with small sharp points in their ends, which lay hold of the edges, or selvages, of the cloth.

These pieces are connected by a cord passing obliquely through holes, or notches, in each piece. By this cord they can be lengthened or shortened, according to the breadth of the web.

They are kept flat after the cloth is stretched by a small bar turning on a centre fixed in one of the pieces of wood. This stretcher is called the templet. Silk-weavers usually stretch their cloth by means of two small sharp-pointed hooks fastened to the ends of two strings, with little weights at the other ends; and the strings are made to pass over little pulleys in each side of the loom, at a suitable distance from the selvages of the cloth.

The perfection of the work depends very much upon the previous operations which the yarn must undergo. It is obvious that the yarns of the warp must be stretched with great parallelism and equality of tension, so that when the cloth is finished, every individual yarn may bear an equal share of any strain which tends to tear the cloth; hence great care must be taken to stretch the yarns of the warp to an equal length, and roll them with great regularity upon the yarn-roll. These operations are called warping and beaming. Previous to warping, the yarn must be prepared by sizing or starching, in order to cement all the loose fibres, and render the yarn smooth.

The spinners of yarn, whether they employ machinery or not, usually reel the yarn into skeins and hanks of a determinate length; and the weight of these hanks, or the number which will weigh one pound, is the denomination for the fineness of the yarn. (See *Manufacture of COTTON.*) In this state the yarn is bought by the weaver. The hanks of yarn are first boiled in water; if it is linen-yarn a little soap and potash are put into the water, and for cotton-yarn a small portion of flour is added, to render the thread firm. When the hanks are perfectly dry they are wound off upon bobbins, each thread having a separate bobbin, and a certain length is wound upon each. This winding is performed by a very simple hand-wheel to turn the bobbin rapidly round, the hanks of yarn being extended upon a reel, or

over two small reels placed at a distance asunder, which are called wisks.

Warping.—The object of this operation is to stretch the whole number of parallel threads which are to form the warp of the cloth to an equal length. For this purpose as many of the above bobbins are taken as will furnish the quantity of threads which is required in the warp of the piece of cloth. The bobbins are usually one-fourth or one-sixth of the number of threads required, and are mounted on spindles in a frame, so that the thread can draw off freely from them. All these threads are drawn off at once, so as to combine them all into one clue, which will be ready for the warp. The ancient method was to draw out the warp at full length, and stretch it in a field; and this is still practised in India and China, but is so very uncertain in our climate that it is seldom used. The present mode of warping is either by the warping-frame or warping-mill.

The warping-frame is a large wooden frame, which is fixed up against a wall in a vertical position. The upright sides of the frame are pierced with holes to receive wooden pins, which project sufficiently to wind the clue of yarns for the warp round them.

The operator having the threads which are to compose the warp wound on the bobbins before-mentioned, places those bobbins in a frame; then tying the ends of all the threads together, and attaching them to one of the pins at one end of the frame, he gathered all the threads in his hand into one clue; and permitting them to slip through his fingers, he walked to the other end, where he passed the yarns over the pin fixed there, and then returned to the former end of the frame and passed the warp over another pin, then went back again, and so on till he formed the required length of the warp. This being done, he secured the end of the warp by crossing it round the pin, and then he worked back and returned over all the same space again, laying the threads over the same pins, so as to double the clue; and he repeated the doubling until the number of threads necessary for the breadth was made up. The number of doublings would be according to the number of bobbins and threads which he took in his hand at once.

This method is used very much in France, particularly at Lyons: it is also used in Devonshire. It is adapted to the weaving carried on in cottages, because the frame is fixed close to the wall, and takes little or no room; but the warping-mill or reel is very superior, and is adopted in all improved manufactures where the warping is a separate business, and is usually done at the mill where the yarn is spun.

The warping-mill is a large reel of a cylindrical form, or rather of a prismatic form, being made with twelve, eighteen, or more sides. The reel is usually about six feet diameter and seven feet high: it is turned round on a vertical axis by a band, passing from a grooved wheel which is turned by a winch, and is placed beneath the seat on which the warper sits. (See a figure of the warping-machine for silk *Plate Silk, fig. 6.*) The bobbins which contain the yarn are placed on a vertical rack suspended from the ceiling, and the threads from them are all collected together and passed between two small upright rollers in a clue, which is wound up by the reel when it is turned round. To guide the clue and distribute it equally on the length of the reel, the above rollers are fixed on a piece of wood, which slides perpendicularly on an upright bar fixed at one side of the reel. The sliding-piece is suspended by a small cord, wrapped round a part of the perpendicular axis that rises above the reel. The cord passes over a pulley at the top of the upright bar, and goes down to the sliding-piece which carries the two rollers. When the reel turns round, the guide-rollers are slowly drawn

WEAVING.

drawn up by the coiling of this cord round the axis; and the yarn is wound in a regular spiral about the reel, until the length which the warp requires is wound upon it. When the full length of the warp is wound on the reel, the clue of thread is crossed over pins projecting from the frame of the reel, and the mill is then turned the reverse way, so that the slider and guide-rollers descend, and the yarn is laid downwards along the same spiral which it before ascended, so as to double the clue of thread; and this doubling is repeated until the required number of threads is collected together in one clue upon the reel.

When the warp is thus completed, it is taken off the reel and wound upon a stick into a ball; the crossings which distinguish the different returns or doublings of the simple clue being first properly secured, as a means of dividing the warp into as many equal portions as is necessary for the convenience of the weaver, in counting the threads in the succeeding operation of beaming.

There is likewise another kind of division of the threads of the warp; this is called the leaf, and serves to separate all the threads which are to go through one of the heddles of the loom, from those which are to go through the other heddle. To effect this separation, the bobbins from which the threads are drawn are arranged in two rows, and a thread is alternately drawn from the upper row and from the lower row. Then at the beginning and end of every doubling of the warp, the threads of one row of bobbins are crossed over the threads of the other row, and two pins are put into the crossings to retain them. These pins are put into holes made in pieces of board fixed to the warping-reel. One of these boards at the top of the reel is fixed fast, but the other is moveable, and can be fixed at any part of the reel, according to the length of the warp.

In the most improved warping-machines, the separation is made by an apparatus called in Scotland the heck. It consists of a row of steel pins with eyes through one end of each for the threads to pass through like large needles. These are stuck into two pieces of wood, by which they are supported in a row near to the warping-reel. Every alternate pin in the row is fastened in one piece of wood, and the intermediate pins are fastened in the other piece, so that by lifting up one piece of wood the pins and threads belonging to it will be raised up, whilst the intermediate pins and threads are held down. This occasions the division of the threads, and a pin is put in to keep them so divided. The other piece of wood is then lifted up, which occasions all the threads to be crossed; that is, every thread forms a cross over that which is adjacent to it. A second pin is then put in, and before the warp is taken off from the reel, this crossing is secured by a string.

Beaming.—When the weaver receives his warp in a large ball or bundle, he proceeds to roll it up regularly upon the yarn-roller of his loom: this is called beaming. For this purpose he employs an instrument called a separator, or ravel, which consists of a number of shreds of cane, fastened together, and fixed to a rail of wood, like the teeth of a long comb; the threads are intended to be put into the spaces between these teeth, so as to stretch the warp to its proper breadth.

Ravels are somewhat like reeds, but much coarser, and are also of different dimensions. One proper for the purpose being found, one of the small divisions of the warp is placed in every interval between two of the teeth. The upper part of the ravel, called the cape, is then put on, to secure the threads from getting out between the teeth, and the operation of winding the warp upon the beam commences. In broad works, two persons are employed to

hold the ravel, which serves to guide the threads of the warp, and to spread them regularly upon the beam; one or two other persons keep the threads at a proper degree of tension, and one more turns the beam upon its centre.

The knottings which secure the crossings or doublings made in warping, are very useful to the weaver in beaming, to ascertain the number of threads, and to distribute them with regularity. He cuts the knotting before he can put the warp in the ravel, but he still keeps them distinct by a small cord.

The French weavers use a small reel, upon which they wind the warp from the ball, and then from this reel they draw off the warp through the ravel, by winding up the beam. The reel is loaded with a weight, to make a regular friction, and draw the warp with a regular tension.

Drawing.—The warp being regularly wound upon the beam, the weaver must pass every yarn through its appropriate eye or loop in the heddles: this operation is called drawing. Two rods are first inserted into the leaf formed by the pins in the warping-mill, and the ends of these rods are tied together; the twine by which the leaf was secured is then cut away, and the warp stretched to its proper breadth. The yarn-beam is suspended by cords behind the heddles, somewhat higher, so that the warp hangs down perpendicularly. The weaver places himself in front of the heddles, and opens the eye of each heddle in succession; and it is the business of another person, placed behind, to select every thread in its order, and deliver it to be drawn through the open eyes of the heddles. The succession in which the threads are to be delivered is easily ascertained by the leaf-rods, as every thread crosses that next to it. The warp, after passing through the heddles, is drawn through the reed by an instrument called a sley, or reed-hook, and two threads are taken through every interval in the reed.

The leaf-rods being passed through the intervals which form the leaf, every thread will be found to pass over the first rod, and under the second; the next thread passes under the first, and over the second, and so on alternately. By this contrivance every thread is kept distinct from that on either side of it, and if broken, its true situation in the warp may be easily and quickly found. This is of such importance, that too much care cannot be taken to preserve the accuracy of the leaf. There is likewise a third rod, which divides the warp into what is usually called *splits*, for two threads alternately pass over and under it; and these two threads also pass through the same interval betwixt the splits of the reed.

These operations being finished, the cords or mounting which move the heddles are applied; the reed is placed in the lay, or batten, and the warp is knotted together into small portions, which are tied to a shaft, and connected by cords to the cloth-beam, and the yarns are stretched ready to begin the weaving.

Manner of Weaving.—The operations of weaving are simple, and soon learned, but require much practice to perform them with dexterity.

In pressing down the treadles of a loom, most beginners are apt to apply the weight or force of the foot much too suddenly. The bad consequences of this are particularly felt in weaving fine or weak cotton-yarn; for the body of the warp must sustain a stress nearly equal to the force with which the weaver's foot is applied to the treadle. The art of spinning has not yet been brought to such perfection as to make every thread capable of bearing its fair proportion of this stress. Besides this, every individual thread is subjected to all the friction occasioned by the heddles and splits of the reed, between which the threads pass, and with which

WEAVING.

which they are generally in contrast when rising and sinking. A sudden pressure of the foot on the treadle must cause a proportional increase of the strokes upon the warp, and also of the friction. As it is impossible to make every thread equally strong and equally tight, those which are the weakest, or the tightest, must bear much more than their equal proportion of the strokes, and are broken very frequently. Even with the greatest attention, more time is lost in tying and replacing them, than would have been sufficient for weaving a very considerable quantity into cloth.

If the weaver, from inattention, continues the operation after one or more warp-threads are broken, the consequence is still worse. The broken thread cannot retain its parallel situation to the rest, but crossing over or between those nearest to it, either breaks them also, or interrupts the passage of the shuttle: it frequently does both.

In every kind of weaving, and especially in thin wiry fabrics, much of the beauty of the cloths depends upon the weft being well stretched. If the motion given to the shuttle be too rapid, it is very apt to recoil, and thus to slacken the thread. It has also a greater tendency, either to break the wool altogether, or to unwind it from the pirn or bobbin of the shuttle in doubles, which, if not picked out, would destroy the regularity of the fabric. The weft of muslins and thin cotton goods is generally woven into the cloth in a wet state.

This tends to lay the ends of the fibres of cotton smooth and parallel, and its effect is similar to that of dressing of the warp.

The person who winds the weft upon the pirn ought to be very careful that it be well formed, so as to unwind freely. The best shape for those used in the fly-shuttle is that of a cone; and the thread ought to traverse freely round the cone, in the form of a spiral, or screw, during the operation of winding.

The same wheel which is used for winding the warp upon the bobbins preparatory to warping, is also fit for winding the weft on the pirn. It only requires a spindle of a different shape, with a screw at one end, upon which the pirn, or bobbin of the shuttle, can be fixed. The wheel is so constructed, that the spindles may be easily shifted, to adapt it for either purpose.

The reeds are formed of a number of short pieces of reed or cane, or of brass wire, fastened parallel to each other between two sticks, and cemented with pitch. This frame is enclosed between two pieces of the frame of the lay, one of which is made wide, to form the shuttle-race; the other piece, which is the lay-cap, extends across the frame, but is fitted so that it can be easily removed to take away the reeds, and substitute a finer or coarser sort, as the nature of the goods to be woven require. The manufacture of reeds, both of cane and of steel, is a separate trade. These are fully described in *Les Arts et Metiers*, vols. 9 and 15.

To render the fabric of the cloth uniform in thickness, the lay or batten must be brought forward with the same force every time.

In weaving some kinds of soft or light goods, the reed is not fixed fast to the lay-cap, but is held in its place by a long thin piece of wood, which is elastic, and yields or springs when the weft is beaten up. In some cases the reed is sustained by a double woollen cord, stretched across the lay, just beneath the lay-cap, and twisted; this bears the reed, and is very elastic, but can be rendered more stiff by twisting the two cords tighter.

In the common operation of weaving, a regular force of the stroke for beating up the weft must be acquired by practice. It is, however, of consequence to the weaver to

mount or prepare his loom in such a manner, that the range or swing of the lay may be in proportion to the thickness of his cloth. As the lay swings backwards and forwards, upon centres placed above, its motion is similar to that of a pendulum. Now the greater the arc, or range through which the lay passes, the greater will be its effect in driving home the weft strongly, and the thicker the fabric of cloth will be, as far as that depends upon the closeness of the weft. For this reason, in weaving coarse and heavy goods, the heddles ought to be hung at a greater distance from the place where the weft is struck up, and consequently where the cloth begins to be formed, than would be proper in light work. The line of the last wrought shot of weft is called by the weavers the fell. The pivots upon which the lay vibrates ought, in general, to be so placed, that the reed will be exactly in the middle, between the fell and the heddles, when the lay hangs perpendicularly. As the fell is constantly varying in its situation during the operation, it will be proper to take its medium; that is, the place where the fell will be when half as much is woven as can be done without taking it up on the cloth-roll, and drawing fresh yarn from the yarn-roll.

The periods for taking up the cloth ought always to be short in weaving light goods; for the less that the extremes of the fell vary from the medium, the more regular will be the arc or swing of the lay. Mr. James Hall had a patent, in 1803, for a method of perpetually winding up the cloth-beam, so as to take away the cloth as fast as it was woven, or shoot by shoot. This was effected in a simple manner by a ratchet-wheel fixed on the end of the cloth-beam, and a proper catch to move it round one tooth at a time: the catch was actuated by the motion of the lay. A similar method is used in ribband-weaving.

The variations in the structure of looms from that which we have described, are not material. The framing is varied in almost every different kind of loom, and ought always to be suitable in strength to the kind of cloth which is to be woven. The loom used for silk is very slight in all its parts; but for carpet and sail-cloth it must be very strong.

In looms for heavy goods, the cloth-beam is not placed at the breast of the weaver, as it is so large that it would impede his working; the cloth is therefore passed over a fixed bar in the place of the cloth-beam represented, and the beam is placed lower down, and near the weaver's feet, out of the way of his knees. The heddles are connected by levers, in some looms, instead of pulleys; but the effect is always the same; *viz.* to make one heddle ascend when the other descends. For weaving fine goods, the heddles would be inconveniently close together, if all the yarns went through two heddles; hence they use four heddles instead of two; but their action is just the same, because they are connected together in pairs, and when one pair rises the other pair sinks. Many looms are still made without the fly-shuttle; and in that case the shuttle is merely thrown from one hand to the other, and then thrown back again: this obliges the weaver to change his hands continually, and the operation is more complicated. For wide cloths, which are more than a man can reach across, two persons were always employed before the fly-shuttle was introduced, which is only within a few years; but by its assistance one person can weave the greatest breadths. The fly-shuttle is the best for all kinds of work, and its construction is so simple that no other ought to be used.

Treatment of different Kinds of Yarns.—The manner of weaving all kinds of plain cloth is much the same, whether it is wool, silk, flax, or cotton; except that the two latter

require what is called *dressing*. Silk and woollen warps require little preparation after being put into the loom, except to clear the yarn occasionally with a comb, to remove knots or lumps which might catch in passing through the reed; the comb detects such lumps, and they are removed with the assistance of a pair of scissors. Flax and cotton, but particularly the latter, require the warp to be dressed with some glutinous matter, to cement the fibres, and lay them close. This is applied in a fluid state, and as the weaving does not proceed well after it is suffered to dry, the warp is dressed with a brush when in the loom, a small quantity at a time, immediately before it is woven.

Dressing.—The use of dressing is to give to yarn sufficient strength or tenacity, to enable it to bear the operation of weaving into cloth. By laying smooth all the ends of the fibres of the raw materials, from which the yarn is spun, it tends both to diminish the friction during the process, and to render the cloth smooth and glossy when finished. The dressing in common use is simply a mucilage of vegetable matter boiled to a consistency in water. Wheat-flour, boiled to a paste like that used by book-binders, or sometimes potatoes, are commonly employed. These answer sufficiently well in giving to the yarn both the smoothness and tenacity required; but the great objection to them is, that they are too easily affected by the action of the atmosphere. When dressed yarn is allowed to stand exposed to the air for any considerable time, before being woven into cloth, it becomes hard, brittle, and comparatively inflexible. It is then tedious and troublesome to weave, and the cloth is rough, wiry, and uneven. This is chiefly remarked in dry weather, when the weavers of fine cloth find it necessary to work up their yarn as speedily as possible, after it is dressed. To counteract this inconveniency, herring or beef brine, and other saline substances which attract moisture, are sometimes mixed in small quantities with the dressing: but this has not been completely and generally successful; probably, because the proportions have not been sufficiently attended to; for a superabundance of moisture is equally prejudicial with a deficiency. The variations of the moisture of the air are so great and frequent, that it is impossible to fix any universal rule for the quantity of salt to be mixed. Some weavers put butter-milk in the paste.

To apply the dressing, the weaver must suspend the operation of weaving, whenever he has worked up that quantity of warp which he has dressed, or within two or three inches; he then quits his seat, and applies the comb to clear away knots and burs; next pushes back the lease-rods towards the yarn-roll, one at a time, and if they slide freely between the yarns, it shews they are clear from knots; he then brushes the yarn with the paste by two brushes, holding one in each hand. The superfluous humidity is afterwards dried by fanning the yarns with a large fan, and then a small quantity of grease is brushed over the yarn; the lease-rods are returned to their proper position, and the weaving is resumed.

Dressing is of the first importance in weaving warps spun from flax or cotton; for it is impossible to produce work of a good quality, unless care be used in dressing the warp.

The same practice, when used upon silk, has a very destructive tendency: it injures the colours of the silk when used, as it is sometimes very improperly, by the weavers of white satin. The injury done to the work is irreparable. In cotton, the operation of dressing is indispensable; but in silk, this is by no means the case.

The preparation of paste or size for warp, has been the subject of several patents. Mr. Foden, in 1799, recom-

mends a quantity of calcined gypsum, or plaster of Paris, to be reduced to a very fine powder, and then mixed with alum, fugar, and the farina or starch of potatoes, or any other vegetable farina. This powder, when mixed well with cold water, forms a soft paste, to which boiling water is to be added, and the mixture thoroughly stirred till it becomes sufficiently gelatinous for use.

Another size, for which Mr. Wilks had a patent in 1801, is prepared as follows:—The starch or flour is to be extracted from any kind of potatoes which are mealy when boiled, by grating them while raw (but washed clean) into a tub of water. The water, thus impregnated with the grated potatoes, is run through a sieve or strainer, which will retain the coarser and fibrous parts of the potatoes, but admit the finer particles, constituting the starch or flour, to pass with the water into a vessel beneath the sieve or strainer. This water must remain in the vessel several hours undisturbed, to permit the starch to subside to the bottom; then the water is poured off, and the starch so obtained is put into fresh water, and passed through a finer sieve into another tub, where the starch is left to subside to the bottom as before, and the water is again poured off.

About two-thirds the quantity of potatoes, which furnished the starch, are also to be boiled without peeling, so as to make them mealy when boiled; they are then mashed, and diluted with water, so that they will pass through a sieve into a boiler. In this the mashed potatoes are heated till they almost boil; and the starch from the grated potatoes is then to be added, and the whole boiled and stirred for 20 minutes, when it will become paste proper for use. It should be spread in a flat open vessel to cool.

Improved System of Weaving by Machinery.—In our article COTTON we mentioned that weaving-looms, worked by mechanical power, were then coming into use: since the time that article was printed these have made great advances; but to use them with advantage, the preparatory processes of warping and dressing must be conducted in a particular manner. Many attempts have been made to diminish the number of operations through which the yarn must pass by combining several together. Mr. Stuart had a patent in 1800 for sizing or starching cotton-yarn whilst in the cop, so that it would be ready to warp at once. Mr. Marland had a patent in 1805 for the same object: his plan was to expose the cops of cotton to the action of the hot starch in an exhausted receiver; the pressure of the atmosphere being thus removed, the size penetrated readily to the centre. It was found difficult to dry the cop perfectly, and the threads were sometimes so glued together as to render the winding off difficult.

Another plan has therefore been introduced both for flax and cotton: this is to wind off the yarn from the cop or bobbin in which it is spun, and gather it upon the bobbins ready for the warping; by this manner the reeling is saved. A small quantity of starch is applied to the yarn during the operation, by causing it to pass over a horizontal wooden cylinder, which revolves on its axis in a trough filled with fluid starch. The threads, in passing from the cop to the bobbin, are drawn over the upper surface of the cylinder, and receive the starch with which it is covered. The winding machine for this actuated a great number of bobbins at once; the warping is then conducted, as we have before described, and the dressing is performed in the loom whilst weaving, that is, if woven by hand; but for the power-loom it is dressed previously to placing it in the loom.

Dressing Machines.—Mr. Johnson, of Stockport, had a patent, in 1804, for a method of dressing whole webs of warp at once,

WEAVING.

once, by a machine. The yarns were wound off from the bobbins or cops of the spinning machines upon beams or rollers. Several of these rollers were placed parallel to each other, in an horizontal direction, at the opposite ends of the machine, from three to six at each end; and the yarns from them were all combined together in one web, which was received and rolled up on the yarn-beam of the loom placed in the middle of the machine, and raised up considerably above the other rollers, so that the yarns proceeded from both ends of the machine towards the middle. In their passage they passed through several reeds to keep them separate, and were supplied with the paste by passing over two cylinders revolving in a trough of fluid paste. This paste was dressed or worked into the yarn by means of two brushes, of a length equal to the breadth of the web; one of the brushes acted upon the upper side of the yarns, and the other on the lower side. A similar pair of brushes were applied at both ends; each brush had a motion given to it by means of cranks, exactly similar to the movement with which the weaver brushes the yarn in the loom. Near the yarn-roller a fan was placed, like that used in a winnowing machine, which blew a current of air through the yarns of the warp to dry them before they were rolled up by the beam. To preserve the lease, the yarns were conducted through a pair of heddles, similar to those of the loom, but they remained slack to avoid friction. The machine was moved by the mill with a constant and regular movement.

When a warp is thus warped, beamed, and dressed, the yarn-beam is carried to a loom, on which the yarn is just exhausted, and is made to replace the empty yarn-roll. The ends of the yarn are joined to the old yarns by twisting, and are thus drawn through the heddles and reed, so that the weaving can be resumed with very little loss of time, and the weaver can proceed with his work without any interruption for dressing. The principal objection to the above machine is the friction which the yarns must undergo in crushing, and in passing through so many reeds: it was, however, practised in a large work at Stockport; but the weaving was performed by hand.

Another dressing machine was invented by Mr. M'Adam, and he obtained a patent in 1806: it is practised by Mr. Monteith, at Pollockshaws near Glasgow. This machine is very much like the former in its manner of action. Instead of using three, four, or six beams at each end of the machine, there are only two beams, each containing one half the number of yarns for the intended warp. The starch is supplied in the same manner as the former, or sometimes by making the two yarn-beams themselves turn in a trough of starch without employing a separate cylinder. The brushing is performed in a more simple and effectual manner by using cylindrical brushes, which revolve with a regular motion, two of them are applied on the upper side of the warp, and two on the lower side; also four fanners are applied to dry the warp instead of one. The yarns were conducted between reeds and through heddles, like the first machine; and hence the same objection of friction applies to both.

Mr. Duncan, in his *Essays on Weaving*, describes another method of dressing warps, which is practised by Mr. Dunlop at Barrowfield. In this the yarn is warped and beamed in the usual manner, upon a yarn-roll: from this the yarn is unwound, and taken up upon another beam; and in its passage from one to the other it is extended, so that the picking and clearing can be performed in the usual way by hand with a comb and scissors, and the dressing is applied with brushes in the usual way: beneath the warp a fan is placed, to blow a current of air up through the yarns and dry them. In this machine all the operations, except the fanning, are

performed by hand; the advantage, therefore, consists only in the division of labour, by making the dressing and weaving distinct operations.

Power-Looms.—In the article *COTTON* we have mentioned Mr. Dolignon's claim to the invention of weaving by mechanical power.

The original project, we believe, was by M. De Gennes, and is published in the *Philosophical Transactions* for 1768, N^o 140. See also Lowthorp's *Abridgment*, vol. i. p. 499. This is a very ingenious invention. The fly-shuttle was not then invented, and he supplied the want of it by a contrivance which held the shuttle as it were in a hand by fingers; this carried it half way through the cloth, and then it was transferred to another similar hand, which drew it through the remainder. By this means there was a greater certainty than in throwing the shuttle from one side to the other, because the shuttle always continued engaged with the mechanism: the whole machine is ingenious and worthy of notice.

M. Vaucanson, the celebrated French mechanist, made a machine for weaving ten ribbands at a time, which was worked by a circular motion given by the workman; and it might, therefore, have been worked by mechanical power. This is described in the *Encyclopede Methodique* in great detail, with ten folding plates, and is an ingenious machine.

We believe both these inventions were prior to that of Mr. Dolignon; and also that the merit of inventing the machine, and first reducing it to practice, is due to Mr. Austin, of Glasgow. In this gentleman's memoir to the Society of Arts, he states, that his first attempt was made in the year 1789, when he entered a caveat for a patent, but did not apply for it further; since that time he made many improvements upon the original plan. In 1796 a report in its favour was made by the Chamber of Commerce and Manufactures at Glasgow; and in 1798, a loom was set at work at Mr. J. Monteith's spinning works, at Pollockshaws near Glasgow, which answered the purpose so well, that a building was erected by Mr. Monteith for containing thirty looms, and afterwards another to hold about two hundred.

Mr. Austin's Power-Loom.—The model from which our drawing (*Plate I. Weaving*) was made, is deposited in the Society of Arts: it is an improvement upon the looms constructed for Mr. Monteith.

The drawing *Plate I.* is a perspective view, exhibiting the whole loom at one glance: it is viewed from the back rather than from the front.

A is a square iron axis extending through the whole length of the machine; to this the power of the first mover is applied by a cog-wheel B, of thirty-six teeth, turned by a pinion of twelve leaves fixed to the axis of the fly-wheel D. A handle is fixed to one of the arms of the wheel to give motion to the model; but in the large machine a live and dead pulley are adapted to the axis of the fly-wheel; and by means of an endless strap, the power is communicated from any convenient part of the mill in which a great number of looms are placed together.

The axis A has several eccentric wheels or camms fixed upon it; as these revolve they give motion to a number of levers or treadles, by which all the usual operations of the loom are performed at the proper intervals: these are,

First, To separate the two parts of the yarns of the warp, as shewn at G, and admit the passage of the shuttle.

Secondly, To throw the shuttle, in order to lay the weft or cross-threads of the cloth.

Thirdly, To move the lay 7, 8, and return it; so that the reed g will beat up the weft close to the fell, or preceding

ceding shoot of the weft: this renders the cloth of uniform texture.

Fourthly, To wind up the cloth upon the cloth-roll, as fast as it is formed by the preceding operations.

The yarns, which are to form the warp of the cloth, are warped in the manner before described upon the yarn-roll *F*; and from thence they are extended horizontally to the cloth-roll *E*, of which only a small part can be seen at the opposite side of the loom: in their way the yarns pass through the eyes of the heddles *G H*, which effect the first operation above-mentioned. Each heddle is composed of a number of perpendicular threads equal to half the number of yarns in the warp; these are stretched between two small rods *aa* and *bb*, and in the middle of each thread is a small eye, through which a yarn of the warp is passed; thus, the first yarn of the warp is passed through the eye of the heddle *G*, but has no connection with the heddle *H*, because it passes between its threads. The second yarn is put through the eye of the heddle *H*, but has no connection with *G*; the third yarn is attached to *H*; the fourth to *G*, and so on alternately throughout the whole number. By this means if one heddle is raised up, and the other at the same time depressed, a separation of the yarns will take place as shewn at *G*, every other yarn being raised up, whilst the intermediate ones are drawn down, so as to admit the passage of the shuttle and weft between them.

The two heddles are moved by camms upon the main axis *A*; and they are so connected by short levers *I I*, which are suspended from the upper part of the loom, that when one heddle is pulled down, the other will be drawn up at the same time, because they are suspended from the opposite ends of the levers *I*.

The camms on the main axis for the heddles are marked *L*; the two are exactly similar, but are reversed upon the axis; that is, the shortest radius of one is placed on the same side with the longest of the other. They act upon two levers, which are the same as the treadles in a common loom; only one of these treadles or levers (*viz.* that which belongs to the camm *L*) can be seen at *M*, the other lever being concealed from the view; both levers move on centres at *n* between the small uprights *dd*; the other ends slide freely up and down between similar uprights at the opposite side of the frame, which cannot be seen in the figure; the levers are connected with the heddles, which being suspended from the levers *I* as before mentioned, the levers will therefore move in contrary directions, the one rising when the other is pressed down by the action of the camm on the axis *A*.

The connection between the levers or treadles *M* and the heddles *G H*, is made by cords communicating with two counter-levers *O P*, which are centered in uprights supported by the frame at the ends of the machine. The counter-levers *O P* are connected with rods *b* and *k*, and these by a double cord are attached to the heddle-rods *aa* and *bb*.

This machinery which we have now described effects the separation of the warp thus: when the axis *A* turns round, every revolution of its camms *L* will cause two separations of the warp, and each one in a different manner, for those yarns which are raised up at one time are drawn down the next.

The second operation, *viz.* throwing the shuttle, is performed by two camms *R S*, which are reversed to each other upon the axis *A*. They act upon two levers, only one of which can be seen at *T*; they are placed beneath the camms. The shuttle requires to be projected with a sudden jerk; these levers are therefore centered at *d* on the

same pin as the levers *M* and *N*, but the other ends press down smaller levers *W*, which are centered at the opposite end of the frame, and lie beneath the long levers. The extreme ends of these smaller levers are connected by a strap *f* with a segment of a wheel, which has a long stem of whalebone *Y* fastened to it; and by means of two strings, one of which is shewn at *g 4*, it moves the peckers or drivers *z* upon the wires *3, 3*, and throws the shuttle. The shuttle, which is shewn in a separate figure, is pointed at each end, and shod with iron: it contains two small rollers *31* upon which it runs; and as they project through both surfaces, it will run either way upwards, or either end first. In the centre of the shuttle is an oblong mortise, containing the pirn or bobbin *33*, on which the thread for the weft of the cloth is wound; and the end of the weft marked *34*, is brought through a small glass tube, called the eye of the shuttle.

The action of the mechanism for throwing the shuttle is as follows:—By the revolution of the camm *R*, the long lever beneath it is depressed, and at the same time the extremity of the shorter lever *W* descends, but with an increased velocity; this by means of the strap *f* turns the segment of a wheel on its centre, and its tail *Y* snatches the string *g 4* of the pecker *z*, and makes it strike against the shuttle with such a velocity, as to drive the shuttle out of the trough *Q*, across the shuttle-race, into the opposite trough, where it will push back the pecker, and remain at rest in the trough ready for the next stroke: by this stroke it will be returned back again with an action similar to the last, but occasioned by the other camm *S*, and its corresponding levers.

The threads of the warp, which are lowest when the separation takes place, are drawn down by their heddle *G* or *H*, so as to lie close upon the shuttle-race, and cause no obstruction to the passage of the shuttle. To facilitate this, the shuttle must be very smooth on the surface, that it may not catch the threads and be stopped. The shuttle-race is inclined towards the reed, both that the yarn may lie flat upon it, and that the shuttle may not be liable to run off its race; for as it leaves the weft, which is drawn off from its bobbin, in the space between the divided yarns of the warp, it might be drawn off its race sideways, without this precaution. In this manner the second operation is performed.

The third motion is that of the reed *g*: this is fixed close behind the shuttle-race, and is a frame containing a great number of parallel slips of reed or cane; between these the yarns of the warp pass, and when the whole frame of reeds is moved towards the cloth-roll *E*, they will act in the manner of a comb, to beat up the thread of the weft, which is left by the shuttle lying loosely between the yarns of the warp.

For this purpose, the shuttle-race, reeds, peckers, &c. and their stem *Y*, with its segment of a wheel, are all placed on a framer which moves on hinges at the lower ends, *8*, of the two upright slides *7 8*. This frame, which is termed the lay, is drawn backwards by means of straps *10, 10*, rolled upon pulleys *11*, fastened upon the axis *12*; upon this same axis are two other smaller pulleys, upon which two straps, *13*, are rolled, to connect with the long levers *14*, which are moved by the camms *15*, upon the axis *A*.

The long levers, *14*, are centered at one end of the frame, and the pulleys on the axis, *12*, being of different diameters, the motion of the reeds will be performed very quickly. To move the lay in a contrary direction, and give the stroke to beat up the weft, two large weights, like *m*, are suspended by straps from pulleys on an horizontal axis, which carries two larger wheels *x*; on these, straps are wound, to communicate

WEAVING.

nicate with the upright sides, 7 8, of the lay, and draw it forwards.

When the loom is acting very quickly, these weights would not act with sufficient sharpness to throw the reeds against the threads of the weft with the proper force.

The weights are therefore connected by spiral wire-springs, with long levers 16, which are pressed down by a camm or rather tappet 17, fixed on the main axis. These levers act before the lay is at liberty to move, and by pressing down the levers extend the springs; consequently, as soon as the camm 15 suffers the lever 14 to rise, the springs act instantaneously, to throw the lay and the reeds forwards to beat up the weft.

The instant after the blow has been given, the lay is drawn back again by the camm 15, and returned into the vertical position, in which situation the lay must continue whilst the shuttle is thrown; for this purpose, the out-sides of the camms 15 are portions of circles. This completes the third motion.

As fast as the cloth is fabricated by the foregoing movements, it is gathered upon the cloth-roll E. This is turned slowly round by a small crank 19, on the extreme end of the main axis A; the crank moves a small rod 20 up and down, in order to turn a small ratchet-wheel round one tooth each revolution of the main axis; the return of the ratchet is prevented by a click. On the axis 21 of the ratchet-wheel is an endless screw, to engage the teeth of a cog-wheel upon the end of the cloth-roll, and give it a slow motion.

The yarn is kept to a proper degree of tension by the friction occasioned by a line 28 passed twice round the yarn-roll, one end being fastened to the frame, and the other to a lever 30, loaded with a weight.

The framing of the loom is too evident to need description. In the construction of the machine, the principal circumstance to be attended to, is the figure of the different camms; also that they are placed upon the axis A in the proper positions relative to each other. These cautions will ensure the accurate performance of the machine.

The camm R or S, for throwing the shuttle, is formed with a sudden beak or projection, that it may strike the levers T down instantaneously, and throw the shuttle; from this beak the curve continues circular for some distance, that the lever may be held stationary; the remainder of the camm gradually diminishes its radius like a spiral, and quits the lever, in order to leave it at liberty to rise up when its corresponding lever is forced down by the beak of the other similar camm S.

The camm L for the heddles is made circular where it is to come in contact with the lever, and which is all the time it is in action. This occasions the levers and heddles to be stationary whilst the shuttle is thrown.

The inventor states that, by the addition of some simple improvements, his looms have the following advantages; *viz.* 300 or 400 of them may be worked by one water-wheel, or steam-engine, all of which will weave cloth in a superior manner to what can be done in the common way. They will go at the rate of 60 shoots in a minute, making two yards height of what is called a nine hundred web in an hour. They will keep regular time in working, stop and begin again, as quick as a stop-watch. They will keep constantly going, except at the time of shifting two shuttles, when the weft on the pirns is exhausted. In general, no knots need be tied, and never more than one in place of two, which are requisite in the common way when a thread breaks. In case the shuttle stops in the shed, the lay will not come forwards, and the loom will instantly stop work-

ing. They will weave proportionally slower or quicker, according to the breadth and quality of the web, which may be the broadest now made. They may be mounted with a harness or spot-heddles, to weave any pattern, twilled, striped, &c.

There is but one clove shed, the same in both breadths, and the strain of the working has no effect on the yarn behind the rods.

The fell and temples always keep the same proper distance. There is no time lost in looming, or cutting out the cloth; but it is done while the loom is working, after the first time.

The weft is well stretched, and exactly even to the fabric required.

Every piece of cloth is measured to a straw's breadth, and marked where to be cut at any given length.

The loom will work backwards in case of any accident, or of one or more shoots missing. Every thread is as regular on the yarn-beam as in the cloth, having no more than two threads in the runner. If a thread should appear too coarse or fine in the web, it can be changed, or any stripe altered at pleasure. They will weave the finest yarn more tenderly and regularly than any weaver can do with his hands and feet.

When a thread, either of warp or weft, breaks in it, the loom will instantly stop, without stopping any other loom, and will give warning by the ringing of a bell. A loom of this kind occupies only the same space as a common loom; the expence of it will be about half more; but this additional expence is more than compensated by the various additional machinery employed for preparing the yarn for the common loom, and which this loom renders entirely unnecessary.

The preparatory processes of reeling, winding, warping, beaming, and looming, and the interruptions occasioned by combing, dressing, fanning, greasing, drawing bores, shifting heddles, rods, and temples, which is nearly one-half of the weaver's work, do not happen in these looms. The general waste accompanying the above operations is stated at about six *per cent.* of the value of the yarn, all which occur in the operations of the common loom. The power-loom, without further trouble, performs every operation after the spinning, till the making of the cloth is accomplished, by which a saving is effected of about 20 *per cent.* of the yarn.

The heddles, reed, and brushes, will wear longer than usual, from the regularity of their motion. More than one-half of workmanship will be saved; one weaver and a boy being quite sufficient to manage five looms of coarse work, and three or four in fine work.

Mr. Miller's Power-Loom.—A patent was taken out for this in 1796. It is so much like Mr. Audin's in its general principle, that it is unnecessary to enter into the description. The motions are all produced by camms fixed on a horizontal axis, and operate upon a number of horizontal levers, disposed beneath the loom, in the situation of treadles: in other respects the arrangement of the parts is very different. This is sometimes called the wiper-loom, wiper being a different name for a camm.

Crank Loom by Power.—In this the treadles are actuated by cranks, instead of camms or wipers. The reciprocating motion produced by a crank is not uniform, but accelerated at one time, and retarded at another. This is an advantage in some of the operations of a loom. It is true, that, by means of wipers, any required law of acceleration may be produced; but in a crank, the acceleration must proceed according to one law. The superiority of cranks arises from

from the circumstance, that they will communicate motion in both directions; whereas a cam will only push a lever in one direction, and the return of the motion must be made by a spring or counterweight. Now, if this counterweight is too large, it makes unnecessary loss of power and friction; and if it is too small, there is some uncertainty in the return of the lever.

Mr. Todd of Boulton had a patent, in 1803, for improvements in power-looms.

Mr. Horrocks of Stockport had three successive patents for this kind of machinery, in 1803, 1805, and 1813. The machine described in the latter is a crank-loom; that is, the lay is actuated by a crank to beat up the weft. The principal improvement consists in a system of levers, which transmit the action of this crank to the lay, and so modify it, that the lay will advance quickly, and give an effective stroke to the weft, and then withdraw quickly to a stationary position, in which it will remain whilst the shuttle is thrown. The advantages which are stated are, that a large shuttle may be used, sufficient to hold a full-sized cop of weft: the waste and loss of time by renewing the cop will, therefore, be less. From the smartness of the stroke, less weight will be required on the yarn-beam, and this will occasion the heddles to work more lightly, so as to break fewer threads. From the same cause, more threads of the weft may be laid in an inch, and make closer work.

Mr. Johnson of Preston had a patent in 1805, and another in 1807, for a power-loom, in which the warp is stretched on a vertical plane, instead of horizontal, as in former machines. The advantages of this are stated to be, 1st, that it takes less space; 2d, the reed serves for the shuttle-race, because the shuttle runs upon the reed itself, and, therefore, makes no friction upon the yarns; 3d, also in dressing, picking, and clearing the warp, the attendant always remains in front of the machine, and can continue to watch the machine; whereas, in the other looms, he must quit his post in front, and go round behind the looms for these operations. When the dressing is to be applied to the warp, whilst it is in the loom, that part of the warp is conducted horizontally for that purpose, and a fan is applied to dry the warp.

The latest inventions of power-looms are Mr. Peter Ewart's patent, 1813; and Mr. Duncan's loom, which he calls a vibrating loom.

The Indian Loom.—This is a striking contrast to our power-looms; it consists merely of two bamboo rollers, one for the warp, and the other for the finished cloth; and a pair of heddles. The shuttle performs the double office of shuttle and reed: for this purpose, it is made like a large netting-needle, and of a length somewhat exceeding the breadth of the piece of cloth which is to be woven.

This apparatus the weaver carries to any tree which affords a shade most grateful to him: under this he digs a hole large enough to contain his legs, and the lower part of the gear or heddles; he then stretches his warp, by fastening his bamboo rollers at a due distance from each other on the turf, by wooden pins; the balances of the gear or heddles he fastens to some convenient branch of the tree over his head; and two loops underneath the gear, in which he inserts his great toes, serve instead of treadles; his long shuttle, which performs also the office of a batten, draws the weft, throws the warp, and afterwards strikes it up close to the web. In such looms as this are made those admirable muslins, whose delicate texture the Europeans can never equal, with all their complicated machinery.

The weaving, even of their finest muslins, is thus conducted in the open air, exposed to all the intense heat of

their climate. We know well that this would be impracticable with fine work in this country, even in an ordinary summer day, on account of the sudden drying of the dressing. It is not known what is the substance which the Indian weavers employ for dressing their warps. It might be of use to our manufacturers, were this investigated in a satisfactory manner. It is said to be a decoction of rice, formed by boiling the rice in a small quantity of water, and expressing the juice: when this is cool, it forms a thick glutinous substance, which undergoes some kind of fermentation before it is used.

Figure-weaving.—Having given an account of the nature and process of plain weaving, we must notice the fanciful and ornamental parts of the business. The extent to which this species of manufacture is carried renders it an object of very great national importance, and deserving a more minute description than our limits will admit.

Figures or patterns are produced in cloth, by employing threads of different colours, or of different appearance, in the warp, or in the weft. By the weaving, the threads must be so disposed, that some colours will be concealed and kept at the back, whilst others are kept in the front; and they must occasionally change places, so as to shew as much of each colour, and as often as it is necessary, to make out the figure or pattern.

The weaver has three means of effecting such changes of colour: First, by using different coloured threads in the warp, or threads of different sizes and substances; these are arranged in the warping, and require no change in the manner of weaving. This is confined to striped patterns, the stripes being in the direction of the length of the piece.

Secondly, by employing several shuttles charged with threads of different colours or substances, and changing one for another every time a change of colour is required. This makes stripes across the breadth of the piece; or, when it is combined with a coloured warp, it makes chequered and spotted patterns of great variety.

Thirdly, by employing a variety of heddles, instead of two, as we have hitherto described; each heddle having a certain portion of the warp allotted to it, and provided with a treadle. When this treadle is depressed, only a certain portion of yarns which belong to that heddle will be drawn up, and the rest will be depressed; consequently, when the weft is thrown, all those yarns which are drawn up will appear on the front or top of the cloth; but in the intervals between them, the weft must appear over those threads which are depressed. The number of threads which are thus brought up may be varied as often as the weaver chooses to press his foot upon a different treadle, and by this he produces his pattern.

All these means may be combined together, and give the weaver the means of representing the most complicated patterns.

The principal varieties of woven cloth, including only those which require a different process for their fabrication, are the following:

Stripes are formed upon the cloth either by the warp or by the woof. When the former of these ways is practised, the variation of the process is chiefly the business of the warper; but in the latter case, it is that of the weaver, as he must continually change his shuttle.

By unravelling any shred of striped cloth, it may easily be discovered whether the stripes have been produced by the operation of the warper or those of the weaver.

When the fly-shuttle is used, the changing of the shuttle is very readily effected by a simple contrivance. One of the shuttle-boxes or troughs, as we have before called them,

(*Plate II. Weaving, fig. 2.*) is made in two parts, so that a part of the trough I near the pecker, where the shuttle lies during the time it is at rest, can be removed, and another trough substituted, which contains a different shuttle. For the purpose of making the change with facility, a moveable shuttle-box *n* is suspended by two perpendicular stems *o* from a wire or centre of motion *m* attached to the lay, as is shewn by the dotted lines. The moveable box is just on the same level with the shuttle-trough I, and is divided by partitions into two or three separate troughs, each exactly the width of the regular trough, and as long as is necessary to contain a shuttle. The pecker *k*, and the wire upon which it slides, remain exactly as before described; but by swinging the moveable box *n* on its centre any one of its compartments may be brought to line with the real place for the shuttle-trough in which the pecker runs. The moveable box must have proper catches to hold it exactly in its true positions.

In working with this contrivance a shuttle of a different colour must be placed in each cell or division of the moveable box *n*; and when the weaver desires to change the shuttle he pulls the connecting string. This moves the shuttle-troughs either backwards or forwards, so as to carry away that shuttle which had been just before in use, and place another before the pecker. Then if he pulls the pecker-handle *y* the new shuttle will be thrown across the shuttle-race, just as the old one was in the former instance. If only one moveable shuttle-box is used there will be some limitation in the pattern, because the stripes of different colour must always consist of an even number of the same coloured thread, as two, four, six, &c. This may be obviated, and a greater change of shuttles may be introduced, by using two moveable shuttle-boxes, one at each end of the shuttle-race: in that case the two moveable boxes are provided with cranks and strings, so that the weaver can reach either of them with ease.

Checks are produced by the combined operations of the warper and the weaver.

Tweeled cloths are so various in their textures, and so complicated in their formation, that it is difficult to convey an adequate idea of the mode of constructing them without the aid of several drawings.

In examining any piece of plain cloth, it will be observed that every thread of the weft crosses alternately over and then under every thread of the warp which it comes to; and the same may be said of the warp: in short, the threads of the warp and weft are thus interwoven at every point where they cross each other, and are therefore tacked alternately.

Tweeled cloth is rather different, for only the third, fourth, fifth, sixth, &c. threads cross each other, to form the texture.

Hence two, three, four, or more, of the successive threads or shoots of the weft will be found to pass under or over the same thread of the warp; or, in other words, by tracing any thread of the warp it will be found to pass over two, three, four, or more threads of the woof at once, without any interweaving the warp. Then it crosses and passes between the threads of the weft, and proceeds beneath two, three, four, or more threads, before it makes another passage between the threads of the weft.

Tweeled cloths are of various descriptions, and produce different kinds of patterns; because at all the intersecting points where the threads actually cross or interweave both threads of warp and weft are seen together, and these points are therefore more marked to the eye, even if the warp and weft are of the same colour. These points in plain tweels form parallel lines extending diagonally across the breadth of the cloth, with a different degree of obliquity, according to the

number of weft-threads over or under which the warp-threads pass before an intersection takes place. In the coarsest kinds every third thread is crossed: in finer fabrics they cross each other at intervals of four, five, six, seven, or eight threads; and in some very fine tweeled silks the crossing does not take place until the sixteenth interval.

Tweeling is produced by multiplying and varying the number of heddles, or, as the weavers express it, the number of leaves in the harness, which is the name given to the whole number of heddles employed in a loom; by the use of a back-harness or double-harness, by increasing the number of threads which pass through each split of the reed, and by an endless variety of modes in drawing the yarns through the heddles; also by increasing the number of treadles, and changing the manner of treading them.

The number of treadles requisite to raise all the heddles which must be used to produce very extensive patterns, would be more than one man could manage; for if he placed his foot by mistake on a wrong treadle he would disfigure his pattern. In these cases, recourse is had to a mode of mounting or preparing the loom, by the application of cords to the different heddles of the harness; and a second person is employed to raise the heddles in the order required, by pulling the strings attached to the respective heddles of the back-harness, and each heddle is returned to its first position by means of a leaden weight underneath. This is the most comprehensive apparatus used by weavers, for all fanciful patterns of great extent, and it is called the *DRAW-LOOM*. See that article.

The manner of mounting the harness of looms, to produce all the principal varieties of fabrics, is detailed in our articles *DESIGN, DRAUGHT, and CORDING of Looms*; also *DAMASK, DIAPER, DIMITY, DORNOCK, FUSTIAN, and TAPESTRY*. A perusal of those articles will render it unnecessary for us to proceed farther on that subject in the present article. We shall however describe a most valuable invention, which has of late years come into use, as a substitute for the second person or draw-boy, who must be employed in the draw-loom, by which loom alone all the complicated patterns can be woven.

Machine called the Draw-Boy, because it performs the Office of a Draw-Boy in Weaving.—The saving of labour is not the only advantage of this machine; the certainty of its operation and security from mistake are obvious. The weaver produces the required action upon the most complicated harness by two treadles only, which he works alternately, just with the same motion as in plain cloth-weaving. The machine, when once set up, performs every thing else.

Like most other inventions, this was at first imperfect, but has been gradually improved. We do not know its history, but we have seen great numbers of machines, for carpet-weaving and coarse goods, which have been some years in use. The machine is situated in a small square frame, not larger than a chair, which stands at the side of the loom, and cords from all the different heddles are conducted from the draw-loom down to this frame, where they are arranged in order. Each cord has a knot answering to the handle, which the boy must pull in the common draw-loom; and there is a piece of mechanism actuated by the treadles which at every stroke selects the proper cord, and draws it down so as to raise the heddles belonging to it. The next time it changes its position and takes another cord, and so on until the whole number of cords has been drawn and the pattern completed.

These original machines have a great defect, *viz.* that they only proceed with regularity to raise up all the heddles, until all the cords have been drawn, and one series of changes

has been gone through; but when this is completed, and a repetition of the pattern is wanted, the weaver must stop and restore the machine to its original position by pulling a string. This appears very easy, but it diverts his attention; and if he does not do it at the exact moment his pattern may be spoiled. This defect was remedied by Mr. Alexander Duff, who received a small and inadequate premium from the Society of Arts in 1807, probably because they were not aware of its value and importance; but in 1810 we find them with a liberality truly discouraging to real merit, giving an equal reward to another person, for the most trivial alteration of Duff's machine. The latter machine is alone described in their Transactions; see vol. xxviii.

Mr. Duff's Draw-Boy.—*Fig. 4. Plate II. Weaving,* is a plan of this machine, and *fig. 2.* a perspective view. It is fixed at the side of a draw-loom, in the same place as a draw-boy would stand, and H shew the cords which are to draw the harness. The same letters are used in both figures. A A is a square wooden axis, mounted so as to turn backwards and forwards in the frame B B, on points or centres of motion. At one end of it a pulley D is fixed, to receive a line *aa* fastened to it at the highest point, by means of which the axis receives motion from the two treadles of the loom, one of the treadles being attached to one end of the line, and the other to the opposite end of it. E E are two rails of wood, fixed across the frame parallel to the axis; and *ee* are two brass plates screwed to the rails, and pierced with a great number of holes to receive as many cords. Each cord is tied by one end to a central rail F of the frame beneath the axis; and after passing through one of the holes in the above plate *e*, and turning over a round wooden rod G, has a lead weight suspended to the other end of it. These weights are shewn at *bb*. The rods G G are suspended by strings at their ends from the ceiling of the room. To each of the above cords another is tied just before it passes over G. These are represented by H, and hang loosely. The upper ends of these cords are tied to horizontal cords extended across the ceiling of the room, and made fast to the ceiling at one end; the other ends pass over pulleys situated at the top of the loom, in a frame called the table of mullets, and the harness or heddles are suspended by them.

By this arrangement it will be seen, that when any one of the cords fastened at F is pulled down, it must draw one of the strings H, and raise such an arrangement of the harness or heddles as is proper to produce the figure which is to be woven. The weight *b* draws the cord so as to keep it straight; all that is therefore necessary is to draw down the cords at F one at a time, but to take a different one each time, and thus raise a different series of the heddles each time; this is the business of the machine, and which it accomplishes in the following manner.

The bar, or axis, A A, has an iron femicircle, *d*, grooved like a pulley, and each of its ends divided, so as to form a cleft-hook or claw.

Each of the strings made fast at F has a large knot tied in it, just beneath where it passes through the brass plate *ee*, and which knot stops the farther ascent of the cord, in consequence of the pull of the weight *b*. Now when the axis A vibrates backwards and forwards by the treadles of the loom, as before mentioned, the hook of the femicircle *d* seizes the knot of one of the cords F, and draws down that cord, and raises the heddles belonging to it. The weaver throws the shuttle, and then returns the treadles, and the axis A with the femicircle returns back again, and allows the cord F to take its original position. When the femicircle *d* inclines over to the other side, its opposite hook

takes hold of the cord F, which is next to the one opposite to that which it just quitted; it draws down this cord, and the weaver again throws his shuttle, then returns the femicircle to the opposite side, and it will take the cord next to the opposite one, and so on; so that the femicircle will in succession take every alternate cord in each of the rows *ee*, and leave every other.

This is effected by the femicircle sliding along its axis A every time, by means of two wooden racks, *b* and *i*, in the plan, which are let into grooves in the axis A; these racks have teeth like saws, but inclined in contrary directions. The racks move backwards and forwards in their grooves, the extent of a tooth at each vibration of the axis, by the action of two circular inclined planes of iron fastened to the frame at L M, against which the ends of the racks are thrown by spiral springs concealed beneath each rack. The femicircle is fixed on a box or carriage N, which slides upon the axis A, and has two clicks upon it; one at *l*, which falls into the teeth of the rack *b*; the other at *m* for the rack *i*: *n* is a roller fixed over the box, and connected with the two clicks *l* and *m*, by threads wound in opposite directions; so that one click is always raised up, and disengaged from its rack, while the other is in action. O is a piece of wire fixed to the frame, so as to intercept a small wire projecting from the roller when the axis is inclined, and turn the roller a small quantity; P is another wire for the same purpose, but fixed to a cross bar, Q, which is moveable, and can be fastened at any required place, farther or nearer from the end of the axis. Suppose the roller *n* to be in such a position that the click *m* is down, and *l* drawn up, the action will be as follows: the femicircle first inclines to the direction of *fig. 2.*, its hook taking down one string; during this motion the end of the rack *i* comes to the inclined part of the circular inclined plane M, and moves by its spring towards D, the space of one tooth, which the click *m* falls into. On the return of the axis, the rack *i* is thrust back, and the box N and femicircle with it towards L, causing the hook to take the next opposite string: in this manner it proceeds, advancing a tooth each vibration, till it gets to the end of its course; the tail of the roller *n* then strikes against the pin P, and turns the roller over, raises the click *m*, and lets down the other, *l*, into the teeth of the rack *b*; this was all the time moving in a contrary direction to *i*, by its inclined plane L, but had no action, as its click *l* was drawn up; this being let down, the femicircle is moved back, a tooth at a time, towards M, until it meets O, which upsets the roller *n*, and sends the femicircle back again.

Tweeled Silks.—In weaving very fine silk tweels, such as those of sixteen leaves, the number of threads required to be drawn through each interval of the reed is so great, that if they were woven with a single reed, the threads would obstruct each other in rising and sinking, and the shed, or opening of the divided warp, would not be sufficiently open to allow the shuttle a free passage. To avoid this inconvenience, other reeds are placed behind that which strikes up the weft; and the warp-threads are so disposed, that those which pass through the same interval in the first reed are divided in passing through the second, and again in passing through the third. By these means the obstruction, if not entirely removed, is greatly lessened.

In the weaving of plain thick woollen cloths, to prevent obstructions of this kind arising from the closeness and roughness of the threads, only one-fourth of the warp is sunk and raised by one treadle, and a second is pressed down to complete the shed between the times when every shot of weft is thrown across.

Double Cloth is composed of two webs, each of which consists

WEAVING.

consists of separate warps and separate wefts, but the two are interwoven at intervals. The junction of the two webs is formed by passing each of them occasionally through the other, so that any particular part of both warps will be found sometimes above and sometimes below.

This species of weaving is almost exclusively confined to the manufacture of carpets in this country. The material employed is dyed woollen, and as almost all carpets are decorated with fanciful ornaments, the colours of the two webs are different, and they are made to pass through each other at such intervals as will form the patterns required. Hence it happens that the patterns at each side of the carpet are the same, but the colours are reversed. Carpets are usually woven in the draw-loom, or with the machine called the draw-boy before described.

Marfeilles is a fabric woven of cotton, which is a double cloth. The loom for weaving *Marfeilles* is somewhat similar to the diaper loom. A good idea of the manner in which it is prepared may be had, by conceiving two webs woven one under the other in the same loom, which are made to intermingle at all the depressed lines, and form the reticulations on the surface, in imitation of the quilting performed by hand.

When the species of *Marfeilles*, called *Marfeilles* quilting, is made, a third warp, of softer materials than the two others described, lies between them, and merely serves as a sort of stuffing to the hollow squares formed by them.

Quilting is another sort of cotton stuff, solely appropriated to quilts, which should, in strictness, be set down exclusively to the cotton manufacture, although there is nothing to prevent its being made of other materials.

The weft of those quilts is of very coarse and thick yarn, which is drawn out by a small hook into little loops, as it is woven, that are so arranged as altogether to form a regular pattern; every third or fourth shoot of the shuttle, the weaver has to stop to form those loops from a draft, which causes the weaving of those quilts to take up more time than that of any other stuff, except tapestry; which accounts for the greatness of the price at which they are sold, in proportion to the value of the materials of which they are principally composed.

Gauze differs in its formation from other cloths, by having the threads of the warp crossed over each other, instead of lying parallel. They are turned to the right and left alternately, and each shot of weft preserves the twine which it has received.

This effect is caused by a singular mode of producing the sheds, which cannot easily be described without the aid of drawings.

Cross, or *Net Weaving*, is a separate branch of the art, and requires a loom particularly constructed for the purpose.

Spots, brocades, and lappets, are produced by a combination of the arts of plain, tweeled, and gauze weaving, and as in every other branch of the art are produced in all their varieties by different ways of forming the division of the warp by the application of numerous heddles, and their connections with the treadles which move them. Indeed the great skill of the art consists in the proper management of this part of the apparatus of a loom.

Ribband Weaving.—This was formerly performed by a small common loom, weaving one ribband at a time. Ribbands are commonly striped in the length by laying a striped warp, and patterns are produced by changing the colour of the weft occasionally; sometimes an ornamented edging is formed by a succession of open loops at the borders of the ribband. Figured ribbands are also woven by a great number of treadles, but as they rarely extend to a greater number

than the weaver can manage by his feet, they seldom employ a draw-loom.

Engine-Loom for weaving Ribbands.—The weavers at Coventry, which is the principal seat of the ribband trade, universally employ what they call an engine-loom: it is worked by the hands and feet like a common loom, but weaves twelve, sixteen, or even twenty ribbands at once. The shuttles are of course fly-shuttles, and are driven by what is called a ladder, because it is a small frame exactly like a ladder, which slides horizontally in a groove in the lay; and every cross-bar of the ladder acts upon one shuttle in the manner of a pecker: the ladder has a handle to give it motion.

Another peculiarity of this loom is, that the ribbands are taken away as they are woven, with very few interruptions to wind up the work: for this purpose they conduct the warps over pulleys, and the ribbands also, so that both hang down in long loops. These looped parts are conducted through pulleys, which are loaded with weights, and tend always to draw the loops down, and keep the warp tight. The weight which is thus suspended by the finished ribband tends to draw it forwards at every stroke which the lay makes; and the weight which is suspended by the yarn of the warp is drawn up. When these weights have run through their respective courses, the weaver must stop to wind up the finished ribband, and unwind a fresh length of yarn. In some looms this is rendered unnecessary by a simple mechanism, which continually winds up the ribband as fast as it is woven.

In 1801 the Society of Arts rewarded Mr. Thomas Clulow, for an improved loom for weaving figured ribbands.

This loom differs from the common figured ribband-looms in the method of forming the figure, which, in the old mode, was tedious, from the work being stopped, whilst the figure was drawn by hand.

In the present loom, the tire-cords which form the figure are drawn or worked by a cord or leather-strap fixed to the centre-treadle, which strap passes over two vertical and one horizontal pulley to the back of the loom, and has a weight hung to the end thereof. Upon this strap above the weight is fixed an iron, of a bevel or sloping form, which when the strap is pulled up by pressing with the foot upon the treadle, raises a wire-lever placed across the main-wheel of the movements placed vertically, and allows this main-wheel to move one-fourth of its circumference, where it is stopped by an iron pin, placed on its rim, and prevented from returning by a clitch or catch on the edge of the wheel on its right side.

Within the rim of the main-wheel is a small catch-strap connected with the strap above-mentioned; this catch-strap pulls forward the main-wheel one-fourth of its circumference, until it is stopped by the wire-lever and one of the pins on the rim, of which there are four in number in the ground.

There are also four iron pins projecting from the left side of the main-wheel in opposite quarters of it: these act on a hanging lever, to the lower part of which a string is attached, which passes behind the box containing the whole machinery, and raises four clicks or catches on four rollers, which permits any one of the four rollers to run back as the figure may require, each roller by such motion drawing up the number of threads necessary to form the figure, by cords extending from these rollers over pulleys to the pass-cords, which draw the figure.

Machine Loom for Ribbands.—We have before mentioned M. Vaucanson's loom for weaving ten ribbands by a rotatory motion. We do not know that this is in use in this country.

Mr. James Birch invented an improvement on the swivel-loom, so as to weave satin-guard or figured laces, and received a reward from the Society of Arts in 1804.

This loom is worked by a circular motion of the hands, without treadles, or any application of the feet.

A wooden bar, to which the hands are applied, works two cranks on a large iron axle, extending the width of the loom; one crank is near each end of the above axis. A fly-wheel is attached to one of the ends of the axis, to regulate the motion of the machinery; an endless screw is placed upon the axis, works a star-wheel underneath it, which turns a barrel that has a resemblance to that of a hand-organ, and has wooden pegs fixed in different parts around it: these pegs catch upon levers, which draw forward the cords that form the figure, and pull them down by a claw, which secures the cords thus brought within its power, and by those means raise the upper gear connected with the cords.

In this loom fourteen pieces of satin-guard or bed-lace are wove at the same time, either one pattern and breadth, or all of different patterns and breadths, as may be required. The figure may be extended to any number of shoots desired.

The loom takes up no more space than a common swivel-loom, such as is employed in plain-work. It appears to work with ease and expedition, to make good work, and to be easily managed. It does not break or chafe the silk during its working. The weaver can move to any part of the front of the loom to inspect the work, and to continue the motion during that time; and the figure or pattern may be formed double the length of those usually done in the engine-loom. The loom can be stopped when required, at any one shoot of the shuttle; and it will answer to weave articles made of silk, wool, cotton, or linen, or mixtures of those articles, or gold or silver lace, and performs its work in half the time of an engine-loom.

The want of uniformity in the technical phraseology of the art of weaving, and the intricacy of the subject, have compelled us to render our descriptions far more intricate and difficult than they otherwise would have been.

We must acknowledge the assistance which we have derived from the very excellent "Essays on the Art of Weaving," by Mr. Duncan, 1808, in 2 vols. 8vo. It is a most curious and valuable publication, embracing almost every thing necessary to be known concerning the art on which it professes to treat; if we except some of the recent improvements in machine-weaving, which are only slightly noticed.

The French have long excelled in the various branches of figure-weaving; but this is more from dexterity of their weavers than from their machinery. Descriptions and drawings of all looms used by them, with every detail of their structure, will be found in the different articles of L'Encyclopede Methodique, and Les Arts et Metiers, D'Art de Fabriquer le Soie, &c.

WEAVING, Stocking. See STOCKINGS.

WEAUME, in *Geography*, a river of France, which runs into the sea, near Marfeilles.

WEAUS, or WEEAS, Indians dwelling near the head of the river Wabash.

WEAUTENANS, Indians of North America, about N. lat. 40° 20'. W. long. 87° 20'.

WEB, a fort of plexus, or texture, formed of threads interwoven with each other; some of which are extended in

length, and called the *warp*, and others drawn across them, called the *woof* or *west*. See WEAVING *supra*.

WEB is also a technical term for all weavers and bleachers, both in Great Britain and Ireland, for a piece of linen cloth.

WEB, *Spider's*, or *Cob-Web*, is a very delicate and wonderful plexus, which that insect spins out of its own bowels; serving it as a sort of toil, or net, to catch flies, &c. See SPIDER.

For the manner in which the spider spins his web, the admirable mechanism of the parts subservient to it, and the uses of it, see SILK, and *Duility of Spider-WEBS infra*.

Dr. Lister tells us, that, attending nearly to a spider weaving a net, he observed it suddenly to desist in the mid-work; and turning its tail to the wind, it darted out a thread, with the violence and stream we see water spout out of a jet: this thread, taken up by the wind, was immediately carried to some fathoms long; still issuing out of the belly of the animal. By-and-bye the spider leaped into the air, and the thread mounted her up swiftly. After this discovery he made the like observation in near thirty different sorts of spiders, and found the air filled with young and old, sailing on their threads, and doubtless seizing gnats and other insects in their passage: there being often manifest signs of slaughter, legs and wings of flies, &c. on these threads, as well as in their webs below.

Dr. Hulse discovered the same thing about the same time. In a letter of Dr. Lister to Mr. Ray, he thinks there is a fair hint of the darting of spiders in Aristotle, Hist. An. lib. ix. cap. 30. and in Pliny, lib. x. cap. 74. But with regard to their sailing, the ancients are silent, and he thinks it was first seen by him. In another letter to Mr. Ray, dated January, 1670, speaking of the height spiders are able to fly to, he says, "Last October, &c. I took notice that the air was very full of webs; I forthwith mounted to the top of the highest steeple on the minster (in York), and could there discern them yet exceeding high above me."

Duility of Spider-WEBS. M. Reaumur observes, that the matter of which spiders and silk-worms form their threads, is brittle when in the mass, like dry gums. As it is drawn out of their bodies, it assumes a consistence, much as glass-threads become hard, as they recede from the lamp, though from a different cause. The duility of this matter, and the apparatus for this purpose, being much more extraordinary in spiders than in silk-worms, we shall here only consider the former. Something also has already been said of each under SILK.

Near the anus of the spider are five or six papillæ, or teats. The extremities of the several papillæ are furnished with holes, that do the business of wire-drawers, in forming the threads. Of these holes, M. Reaumur observes, there are enough in compass of the smallest pin's-head, to yield a prodigious quantity of distinct threads. The holes are perceived by their effects: take a large garden-spider ready to lay its eggs, and applying the finger on a part of its papillæ, as you withdraw that finger, it will take with it an amazing number of different threads. M. Reaumur has often counted seventy or eighty with a microscope, but has perceived that there were infinitely more than he could tell. In effect, if he could say, that each tip of a papilla furnished a thousand, he is persuaded he should say much too little. The part is divided into an infinity of little prominences, like the eyes of a butterfly, &c. each prominence, no doubt, makes its several threads; or rather, between the several protuberances, there are holes that give vent to threads; the use of the protuberances, in all probability,

bility, being to keep the threads at their first exit, before they are yet hardened by the air, asunder. In some spiders those protuberances are not so sensible; but in lieu thereof there are tufts of hair, which may serve the same office, *viz.* to keep the threads apart. Be this as it will, there may threads come out at above a thousand different places in every papilla; consequently, the spider having six papillæ, has holes for above six thousand threads. It is not enough that these apertures are immensely small: but the threads are already formed before they arrive at the papilla, each of them having its little sheath or duct, in which it is brought to the papilla from a considerable distance.

M. Reaumur traces them up to their source, and shews the mechanism with which they are made. Near the origin of the belly he finds two little soft bodies, which are the first source of the silk. Their form and transparency resemble those of glass-beads, by which name we shall hereafter denote them. The tip of each bead goes winding, and makes an infinity of turns and returns towards the papilla. From the base, or root of the head, proceeds another branch much thicker; which winding variously, forms several knots, and takes its course like the other, towards the hind part of the spider. In these beads and their branches, is contained a matter proper to form the silk, only that it is too soft. The body of the bead is a kind of reservoir, and the two branches two canals proceeding from it. A little farther backwards, there are two other lesser beads, which only send forth one branch a-piece, and that from the tip. Beside these, there are three other larger vessels on each side of the spider, which M. Reaumur takes for the last reservoirs, where the liquor is collected. The biggest is near the head of the insect, and the least near the anus. They all terminate in a point; and from the three points of these three reservoirs it is, that the threads, at least the greatest part of the threads drawn out at the three papillæ, proceed. Each reservoir supplies one papilla. Lastly, at the roots of the papillæ, there are discerned several fleshy tubes; probably, as many as there are papillæ. Upon lifting up the membrane, or pellicle, that seems to cover these tubes, they appear full of threads, all distinct from each other, and which, of consequence, under a common cover, have each their particular one; being kept like knives in sheaths. The immense quantity of threads contained here, M. Reaumur concludes, upon tracing their course, does not wholly come from the points of the reservoirs; but some from all the turns, and angles; nay, probably from every part of it. But by what conveyances the liquor comes into the beads, and out of the beads into the reservoirs, remains yet to be discovered.

We have already observed, that the tip of each papilla may give passage to above a thousand threads; yet the diameter of that papilla does not exceed a small pin's-head; but we were there only considering the largest spiders.

If we examine the young growing spiders produced by those, we shall find, that they no sooner quit their egg, than they begin to spin. Indeed their threads can scarce be perceived; but the webs may: they are frequently as thick, and close, as those of house-spiders; and no wonder: there being often four or five hundred little spiders concurring to the same work. How minute must their holes be? the imagination can scarce conceive that of their papillæ! The whole spider is, perhaps, less than a papilla of the parent which produced it.

This is easily seen; each big spider lays four or five hundred eggs; these eggs are all wrapped up in a bag; and as

soon as the young ones have broke through the bag, they begin to spin. How fine must their threads at this time be!

Yet is not this the utmost nature does: there are some kinds of spiders so small at their birth, that they are not visible without a microscope. There is usually found an infinity of these in a cluster, and they only appear like a number of red points. And yet there are webs found under them, though well nigh imperceptible. What must be the tenuity of one of these threads; the smallest hair must be to one of these what the most massive bar is to the finest gold-wire.

The matter of which the threads are formed, we have observed, is a viscid juice. The beads are the first receptacles where it is gathered, and the place where it has the least consistence. It is much harder when got into the six great reservoirs, whither it is carried by canals from the former; this consistence it acquires in good measure in its passage; part of the humidity being dissipated in the way, or secreted by parts destined for that purpose.

Lastly, the liquor is dried still farther, and becomes thread, in its progress through the respective canals to the papillæ. When these first appear out at the holes, they are still glutinous; so that such as spring out of neighbouring holes stick together. The air completes the drying.

By boiling the spider, more or less, the liquor is brought to a greater or less consistence, fit to draw out into threads; for it is too fluid for that purpose while yet inclosed in its reservoirs.

The matter contained in these reservoirs, when well dried, appears a transparent gum, or glue, which breaks when much bent: like glass, it only becomes flexible by being divided into the finest threads. And probably it was on this account nature made the number of holes so immense. The matter of silk formed in the bodies of spiders being much more brittle than that formed in silk-worms, needed to be wound smaller. Otherwise we do not conceive, why they should form a great number of threads, which were afterwards to be re-united: a single canal might else have done.

The thread of a spider being strong enough to bear five or six times the weight of the spider's body, is composed of several finer threads, that are drawn out separately, but unite together at the distance of two or three hairs' breadth from the body of the spider. The threads are coarser or finer, according to the size of the spider that spins them. Mr. Leewenhoeck computes that 100 of the finest threads of a full grown spider, are not equal to the diameter of the hair of his beard; and consequently, if the hair be round, 10,000 such threads are not bigger than such a hair. He calculated farther, that when young spiders first begin to spin, 400 of them are not larger than one that is full-grown; and therefore the thread of such a little spider is 400 times smaller than the thread of a full-grown one; allowing this, four millions of a young spider's threads are not so big as the single hair of a man's beard.

WEB, in *Ship-Building*, the thin partition on the inside of the rim, and between the spokes of an iron or brass-sheave.

WEB of a *Coulter*, in *Agriculture*, that part of it which is drawn out thin and sharp, in order to cut and separate the ground, in opposition to the others which are thick and blunt. In the sock, too, any thin sharp part has the name of web or wing.

WEB on the *Eye*, among *Animals*, a term sometimes used to signify a film on that part. See EYE, FILM, and *White FILM*.

WEB-Cafe. See CHRYSALIS.

WEB, Pin and. See PANNUS.

WEBB, PHILIP-CARTERET, in *Biography*, a member of the society of antiquaries, was born in 1700, and admitted an attorney in 1724, and distinguished for his acquaintance with the records of the kingdom, and with constitutional and parliamentary law. He was returned in 1754, and again in 1761, as a member for the borough of Haslemere; and being attached to the then existing administration, he obtained the place of secretary of bankrupts in the court of chancery, and in 1756 became one of the joint solicitors of the treasury. He was employed in 1763 in conducting the prosecution against Mr. Wilkes, for writing a number of the North Briton; and printed on that occasion "A Collection of Records about General Warrants," and "Observations on discharging Mr. Wilkes from the Tower." He died at his house in Busbridge, Surrey, in June 1770, and left a valuable library, and curious collection of coins, medals, and relics of antiquity, which were sold by auction. He had sold 30 MSS. of the rolls of parliament to the house of lords, and a number of other MSS. were sold to lord Shelburne, and afterwards to the British Museum. Among his publications we may reckon "A Letter to the Rev. Mr. Warburton, on some passages of his Divine Legation;" "Various Pieces relative to the State of the Law in this Kingdom;" "Account of some Particulars concerning Domesday Book;" "A short Account of Danegeld;" "Account of a Copper Table, discovered near Heraclea." Mr. Webb was twice married, and by his first wife left a son of his own name. Nichols's Lit. Anecd. Gen. Biog.

WEBB Pond, in *Geography*, a town of the district of Maine, in the county of Oxford, containing 318 inhabitants.

WEBBER, JOHN, in *Biography*, who accompanied captain Cook in his last voyage to the South sea, in the capacity of draughtsman, was a native of London, though his father was a Swiss. He was born in 1752, and was sent young to Paris for his education as an artist. After his return he studied at the Royal Academy, of which in 1785 he became a member. His talents for drawing landscape recommended him to the lords of the admiralty, who appointed him to go with captain Cook on his voyage of discovery; and when the vessels returned in 1780, they also commissioned him to superintend the engraving of the prints from his own drawings of the scenes he had beheld. When these were completed, he was permitted to publish a work consisting of other views which he had made, which he etched and aquatinted himself, and published on his own account; and these produced him a handsome remuneration. He afterwards applied himself to painting, but his pictures are weak and unsubstantial, without colour or effect, or any great degree of merit, though they please from their neatness and minuteness. He died in 1793, aged 41.

WEBERA, in *Botany*, owes its name to Schreber, who dedicated this genus to the memory of George Henry Weber, late professor of medicine and botany at Kiel; an excellent cryptogamic botanist, most celebrated for his *Spicilegium Floræ Goettingensis*, published in 1778, and one of the classical books in that department of the science. He died in 1786, at the age of 35. Hedwig had previously commemorated Weber in a genus of Mosses, some species of which are now referred to *Bartramia*, others to *Bryum*. (See MUSCI and FRINGE of Mosses.) It is to be regretted that *Webera* did not take place of *Bartramia*, the person after whom the latter was named, however meritorious, being scarcely at all conversant with mosses.—Schreb. Gen. 794.

Willd. Sp. Pl. v. 1. 1224. Mart. Mill. Dict. v. 4. Ait. Hort. Kew. v. 1. 371. (Chomelia; Linn. Gen. ed. 2. 72.) Class and order, *Pentandria Monogynia*. Nat. Ord. *Rubiaceæ*, Juss.

Gen. Ch. Cal. Perianth superior, of one leaf, divided half way down into five erect, acute, permanent segments. Cor. of one petal, funnel-shaped; tube cylindrical, longer than the calyx: limb in five ovate-oblong, reflexed segments. Nectary a fleshy ring, surrounding the base of the style. Stam. Filaments five, very short, inserted into the margin of the tube; anthers linear, incumbent, spreading. Pist. Germen roundish, inferior; style simple, longer than the tube of the corolla; stigma club-shaped, with ten furrows. Peric. Berry nearly globular, of two cells, crowned with the permanent enlarged calyx. Seeds from two to four in each cell, angular.

Ess. Ch. Calyx superior, in five permanent segments. Corolla funnel-shaped, five-cleft. Stamens in the mouth of the tube. Stigma club-shaped, with ten furrows. Berry inferior, of two cells. Seeds several, angular.

A genus of evergreen East Indian shrubs, with opposite branches and leaves; and axillary or terminal, aggregate flowers, which are occasionally augmented in the number of their divisions and stamens, from five to six. *Canthium* of Lamarck's Dict. v. 1. 602. Juss. 204. Cavan. Ic. v. 5. 21, confounded by Willdenow with this genus, is certainly very distinct in its habit, peltate stigma, solitary seeds, and four-cleft flowers.

1. *W. corymbosa*. Corymbose *Webera*. Willd. n. 1. Ait. n. 1. (*Rondeletia asiatica*; Linn. Sp. Pl. 244. Cupi; Rheede Hort. Malab. v. 2. 37. t. 23. Raii Hist. v. 2. 1494.)

Leaves elliptic-oblong. Corymb terminal, forked, many-flowered.—Native of sandy ground in the East Indies; cultivated by Miller in the stove at Chelsea, in 1759, but it is not recorded by Mr. Aiton to have flowered, nor do we recollect having ever seen the plant in any collection. A wild specimen from Dr. Rottler is before us. The stem is shrubby, about the height of a man, with smooth, leafy, somewhat compressed, branches. Leaves on short thick stalks, entire, coriaceous, very smooth, four inches long, rather acute, with a stout rib, and numerous reticulated veins; their upper side shining; lower paler. Stipules intrafoliaceous, triangular, short, pointed. Flower-stalks hairy. Flowers three-quarters of an inch long, whitish, agreeably fragrant, turning yellowish as they fade. Berries firm, the size of a currant, blackish, sweetish, but not eatable. Rheede describes 7 or 8 seeds in each fruit.

This plant has the appearance of an *Ixora* or *Pavetta*, as we have observed at the end of our article RONDELETIA; but perhaps the stigma, very important in this natural order, may keep it distinct.

2. *W. cymosa*. Cymose *Webera*. Willd. n. 2.—"Leaves ovate, pointed. Cymes axillary, stalked, many-flowered."—Native of the East Indies. "A tree, with round downy branches. Leaves stalked, ovate, obtuse with a point, entire, very smooth, rigid, simply veiny; shining above. Cymes convex. Flower-stalks downy. Corolla half the size of the former. Style much longer than the corolla. Stigma capitate, cloven. Berry the size of Juniper."—Willdenow, from a dried specimen.—We have not seen this species. The description of the stigma does not answer to the generic character.

WEBHAMET, in *Geography*, a river of the district of Maine, which runs into the Atlantic, near Wells.

WEBUCH,

WEBUCH, CAPE, a cape on the E. coast of Labrador. N. lat. $55^{\circ} 21'$. W. long. $58^{\circ} 10'$.

WECHMAR, or WARIHMAR, a town of Germany, in the principality of Gotha; 4 miles S.E. of Gotha.

WECHQUETANK, a Moravian settlement in Pennsylvania; 30 miles N.W. of Bethlehem.

WECHSELBURG, a township of Germany, in the lordship of Schonburg; 4 miles N.N.E. of Penig.

WECHSTEN, a town of Germany, in the county of Verden; 12 miles S.E. of Verden.

WECHTERBACH, a town of Germany, in the county of Isenburg; 7 miles S.E. of Budingem.

WECHTERSWINCKEL, a town of the duchy of Wurzburg; 3 miles N.N.W. of Neustadt am Saal.

WECKHOLM, a town of Sweden, in the province of Upland; 22 miles S.W. of Upsal.

WED EL CASAAB, a river of Algiers, which runs into the Mediterranean, 5 miles S. of Cape Falcon.

WED el Kibbeer, a river of Algiers, anciently called *Ampfaga*, which runs into the Mediterranean, 15 miles S. of Sebba Rous. N. lat. $36^{\circ} 57'$. E. long. $6^{\circ} 28'$.

WED el Mailab, i. e. the *Salt River*, a river of Algiers, which runs into the Mediterranean, 10 miles S.S.E. of Cape Figalo.

WED el Shaier, a river of Africa, which rises about 12 miles E. from the mountain of Zeckar, in the Sahara, and after a north-east course about 30 miles changes its name to Mailah, and finally loses itself in the Short.

WEDDER, the name of a certain state of sheep. See WETHER-Sheep.

WEDDRA, in *Commerce*. See VEDRO.

WEDEKINSTEIN, in *Geography*, a town of Westphalia, in the principality of Minden; 3 miles S.W. of Minden.

WEDEL, GEORGE WOLFFGANG, in *Biography*, an eminent physician, was born in 1645, at Golzan, in Lusatia, and studied physic and took his doctor's degree at Jena, in 1667, where, after a temporary exercise of his profession at Gotha, he became medical professor, in which station he continued with reputation for almost fifty years. He combined with his medical skill a considerable acquaintance with mathematics and philology, as well as with the oriental and classical languages. He was an associate to the Academy Naturæ Curiosorum, and to the Royal Society of Berlin, physician to several German sovereigns, a count palatine, and an imperial counsellor. Notwithstanding these high offices and numerous engagements, he was attentive to the poor, and assiduous in his literary labours. His pathology was derived from the systems of Helmont and Sylvius; in his practice he depended much on absorbents, and the volatile salts of vegetables. Wedel was addicted to astrology; but he is chiefly celebrated for his pharmaceutical knowledge, and his elegance of prescription, so that many of his compositions have been adopted in dispensaries. Of his works, besides his academical dissertations, the principal are the following; viz. "Opiologia;" "Pharmacia in Artis formam redacta;" "De Medicamentorum Facultatibus cognoscendis et applicandis;" "De Morbis Infantum;" and "Exercitationes Medico-Philologicae." Haller. Eloy.

WEDEL, in *Geography*, a town of Holstein; 13 miles N.W. of Hamburg.—Also, a town of the New Mark of Brandenburg; 11 miles E. of Reetz.

WEDELIA, in *Botany*, was so called by Jacquin, in honour of Dr. John Wolfgang Wedel, of Jena, whom he celebrates as a highly meritorious botanist, and who wrote a *Tentamen Botanicum*, published at Jena in 1747, with a preface by his friend Hamberger. The design of this

work is to combine the systems of Rivinus and Linnaeus, the classes of the latter making subdivisions of the former. We presume that no scheme could be less natural or useful, whatever the botanical skill of the author might be; of which indeed we are not disposed to think highly, as he made a point of excluding the fruit from his principles of classification. He wrote a German essay against Haller, on the subject of botanical terms, of which the latter speaks as full of taunts and reproaches. Wedel died in 1757, at the age of 49. Some others of the same name, and probably the same family, who were Professors at Jena, appear full as well entitled to botanical honours; especially George Wolfgang Wedel, who died in 1721, aged 76, and has left behind him numerous dissertations on botany and the materia medica.—Jacq. Amer. 217. Willd. Sp. Pl. v. 3. 2334. Juss. 189. Gært. v. 2. 435. (Alcina; Cavan. Ic. v. 1. 10. Ait. Hort. Kew. v. 5. 164.)—Class and Order, *Syngenesia Polygamia-necessaria*. Nat. Ord. *Compositæ oppositifoliae*, Linn. *Corymbiferae*, Juss.

Gen. Ch. *Common Calyx* simple, of four or five large leaves. *Cor.* compound, radiant. *Florets* of the disk perfect, numerous, funnel-shaped, five-cleft; those of the radius from eight to twelve, roundish-ovate, cloven. *Stam.* in the florets of the disk. Filaments five, capillary short; anthers united into a tube, as long as the partial corolla. *Pist.* in the same florets, Germen minute, imperfect; style thread-shaped, the length of the anthers; stigma simple or divided: in those of the radius, Germen oblong, quadrangular; style thread-shaped; stigmas two, revolute. *Peric.* none, the calyx remaining unaltered. *Seeds* in the disk imperfect; in the florets of the radius solitary, obovate, gibbous, crowned with four, five, or ten teeth. *Recept.* chaffy, slightly convex; the scales ovate, concave, as long as the florets.

Ess. Ch. Receptacle chaffy. Seed-crown of from five to ten teeth. Calyx simple, of four or five leaves.

Obf. This genus is separated from POLYMNIA, (see that article,) on account of its simple calyx, and the presence of a crown to the seeds, which appear to us sufficient characters.

1. *W. frutescens*. Shrubby *Wedelia*. Willd. n. 1. Jacq. Amer. 217. t. 130. (Polymnia *Wedelia*; Linn. Mant. 118. Poir. in Lam. Dict. v. 5. 506.)—Stem shrubby. Leaves distinct, stalked, lanceolate. Seed-crown of ten teeth.—Native of Carthage, South America, in bushy woody places, flowering in July and August. *Stem* shrubby, climbing, with round leafy branches, rough in our specimen with minute points. *Leaves* acute, two or three inches long, somewhat ferrated, bristly on both sides; the upper rough with callous points; lower paler. *Foot-stalks* linear rough, hardly half an inch in length, combined at the base by a narrow annular *stipula*. *Flowers* terminal, stalked, solitary, yellow, near an inch broad, with a rough *calyx*; the outer scales of their *receptacle* looking like a coloured inner calyx. *Seeds*, according to Jacquin, each with a little cup-shaped crown, having about ten teeth.

2. *W. perfoliata*. Perfoliate *Wedelia*. Willd. n. 2. (Alcina *perfoliata*; Cavan. Ic. v. 1. 11. t. 15. Ait. Hort. Kew. v. 5. 164.)—Stem herbaceous. Leaves rhomboid, tapering at the base, perfoliate. Seed-crown of five teeth.—Native of Mexico, from whence its seeds were brought to Madrid, and thence dispersed through the botanic gardens of other parts of Europe. This is an annual plant, with nothing to attract the attention of florists. It flowers late, and does not always ripen seed in England. The *stem* is four feet high, angular or furrowed, leafy, branched, nearly smooth, often purplish. *Leaves* three or four inches long,

long, including their narrow base, pointed, ferrated, triple-ribbed, light green, roughish. *Flowers* yellow, stalked, much smaller than the foregoing. *Calyx* broad, extending far beyond the rays. *Seeds* of the marginal *florets* large, tumid, each crowned with four, five, or more, irregularly placed tubercles, or teeth, not agreeing precisely with the crown of the first species, but scarcely affording sufficient reason to form a generic distinction.

WEDENSCHWEIL, in *Geography*, a town of Switzerland, and principal place of a bailiwick, in the canton of Zurich, on the S.W. coast of lake Zurich; 9 miles S. of Zurich.

WEDGE, CUNEUS, in *Mechanics*, the last of the five powers, or simple machines.

The wedge is a triangular prism, whose bases are isosceles acute-angled triangles.

Authors are divided about the principle whence the wedge derives its power.

Aristotle considers it as two levers of the first kind, inclined toward each other, and acting opposite ways. Guido Ubaldo, Merfennus, &c. will have them levers of the second kind. But Fr. de Lanis shews, that the wedge cannot be reduced to any lever at all.

Others refer the wedge to the inclined plane. Others, again, with De Stair, deny the wedge to have scarce any force at all; and ascribe much the greatest part to the matter that drives it.

Its doctrine (according to some writers) is contained in this proposition. "If a power be applied to a wedge, in such manner, as that the line of direction CD (*Plate XL. Mechanics, fig. 1.*) perpendicular to AB , is to the resistance to be overcome, as AB to CD ; the power will be equal to the resistance."

Or thus: "If the power directly applied to the head of the wedge, be to the resistance to be overcome by the wedge, as the thickness of the wedge is to its height; then the power will be equivalent to its resistance; and, if increased, will overcome it."

In proof of this proposition, they allege, that the firmness by which the parts of the obstacle, suppose wood, adhere to one another, is the resistance to be overcome by the wedge; and that while the wedge is driven into the wood, the way or length it has gone is BH (*fig. 2.*); and DC is the way or length gone in the same time, by the impediment; that is, the parts C and D of the wood are so far divided asunder: and according as the wedge is driven down farther and farther along its height; so the parts C and D of the wood are divided more and more, along the thickness of the wedge.

But Dr. Defaguliers has proved, that, when the resistance acts perpendicularly against the sides of the wedge, the power is to the whole resistance as the length of both sides of the wedge, taken together, is to the thickness of its back.

According to the preceding theory, if the thickness of the wedge (that is, the way of the impediment, and consequently its velocity) be to the height of the wedge (that is, the way, and consequently the velocity of the power) as the power to the impediment, or resistance; then the momentum of the power, and the impediment, will be equal the one to the other: and consequently the power, being increased, will overcome the resistance.

Hence, 1. The power equivalent to half the resistance, is to it as AC to DC , (*fig. 1.*) that is, as the whole sine to the co-tangent of half the angle of the wedge ADC . And 2. As the tangent of a less angle is less than that of a greater, the power must have a greater proportion to half

the resistance, if the angle be greater than if less; consequently, the acuter the wedge is, the more does it increase the power.

The above proportion is adopted by Wallis, (*Op. Math. vol. i. p. 1016.*) Keil, (*Int. ad Ver. Phyl.*) and S'Gravesande (*El. Math. lib. i. cap. 14.*); but S'Gravesande, in his *Scholium de ligno findendo* (*ubi supra*), observes, that when the parts of the wood are separated before the wedge, the force by which it is thrust in is to the resistance of the wood as a line, drawn from a point in the middle of the base to the side of the wedge, and at right angles with the side of the separated wood continued, to the height of the wedge; but when the parts of the wood are separated no farther than the wedge is driven in, the equilibrium will be, when the power is to the resistance as the half base of the wedge to its side.

To this method of estimating the power of the wedge it has been objected that, by allowing each part of the weight to have moved through a space equal to half the back of the wedge, whilst the power has moved through its height, and the whole weight to have moved through a space equal to the whole back, the whole is made to move farther than its parts.

M. Muschenbroeck states the proportion of the power to the weight in a simple wedge, or half the wedge (*fig. 1.*) bisecting it by a plane passing through CD , as its back is to its length, or in that case as AC to CD : and in a double wedge or the wedge ABD , as AB to $2CD$. *Int. ad Phil. vol. i. p. 132.*

Mr. Ferguson estimates the power of the wedge, in the two cases mentioned by S'Gravesande, in the following manner. When the wood does not cleave at any distance before the wedge, there will be an equilibrium (he says) between the power impelling the wedge downward, and the resistance of the wood acting against the two sides of the wedge, if the power be to the resistance as half the thickness of the wedge at its back is to the length of either of its sides; and if the power be increased so as to overcome the friction of the wedge, and the resistance arising from the cohesion or stickage of the wood, the wedge will be drove in, and the wood split asunder.

But when the wood cleaves at any distance before the wedge (as it generally does), the power impelling the wedge will be to the resistance of the wood as half its thickness is to the length of either side of the cleft, estimated from the top or acting part of the wedge: for supposing the wedge to be lengthened down to the bottom of the cleft, the power will be to the resistance as half the thickness of the wedge is to the length of either of its sides; or, which amounts to the same thing, as the whole thickness of the wedge is to the length of both its sides.

In proof of this proportion we may suppose the wedge divided lengthways into two equal parts, and then it will become two equally inclined planes; one of which, as abc (*fig. 3.*) may be made use of as a half-wedge for separating the moulding cd from the wainscot AB . When this has been driven its whole length ac between the wainscot and moulding, its side ac will be at ed , and the moulding will be separated to fg from the wainscot.

From the property of the inclined plane, it appears, that to have an equilibrium between the power impelling the half-wedge and the resistance of the moulding, the former must be to the latter, as ab to ac ; that is, as the thickness of the back which receives the stroke is to the length of the side against which the moulding acts. Consequently, since the power upon the half-wedge is to the resistance against its side, as the half back ab is to the whole side ac , it is plain,

plain, that the power upon the whole wedge (where the whole back is double the half back) must be to the resistance against both its sides, as the thickness of the whole back is to the length of both the sides, supposing the wedge at the bottom of the cleft; or as the thickness of the whole back to the length of both sides of the cleft, when the wood splits at any distance before the wedge. For when the wedge is driven quite into the wood, and the wood splits at ever so small a distance before its edge, the top of the wedge then becomes the acting part, because the wood does not touch it any where else. And since the bottom of the cleft must be considered as that part where the whole stickage or resistance is accumulated, it is plain from the nature of the lever, that the farther the power acts from the resistance, the greater is the advantage.

Some writers have, indeed, advanced, that the power of the wedge is to the resistance to be overcome, as the thickness of the back of the wedge is to the length only of one of its sides; but this, says Mr. Ferguson, seems very strange; for, if we suppose *AB* (*fig. 4.*) to be a strong inflexible bar of wood or iron fixed into the ground at *CB*, and *D* and *E* to be two blocks of marble lying on the ground on opposite sides of the bar; it is evident that the block *D* may be separated from the bar to the distance *d* equal to *ab*, by driving the inclined plane or half-wedge *abo* down between them; and the block *E* may be separated to an equal distance on the other side, in like manner, by the half-wedge *cdo*. But the power impelling each half-wedge will be to the resistance of the block against its side, as the thickness of that half-wedge is to the length of its acting side. Therefore the power to drive both the half-wedges is to the resistances, as both the half backs are to the length of both the acting sides, or as half the thickness of the whole back is to the length of either side. And, if the bar be taken away, the blocks put close together, and the two half-wedges joined to make one; it will require as much force to drive it down between the blocks, as is equal to the sum of the separate powers acting upon the half-wedges when the bar was between them. Ferguson's Lect. p. 40, &c. 4to. See also Defag. Exp. Phil. vol. i. p. 107, &c.

Mr. Ludlam, in an Essay on the Power of the Wedge, printed in 1770, proposes, with a particular view to the machines described by S'Gravesande, Defaguliers, and Ferguson, for estimating the power of the wedge, to determine this power, when two equal forces act on the sides of an isosceles triangle in directions parallel to the back but opposite to each other, and are sustained by a third force acting perpendicularly on the back of the wedge. For this purpose, let *ABC* (*fig. 5.*) be an isosceles wedge, whose angular point is *C*, sides *AC* and *BC*, back *AB*, and perpendicular height *HC*: let *FE* represent the quantity and direction of the force applied to one of the sides; this may be resolved into two other forces *FD* and *DE*, the former parallel and the latter perpendicular to the side *AC*; and the oblique force *FE* will have just the same effect upon the wedge as a less perpendicular force *DE*; the former being to the latter as *AC* is to *HC*. But this last perpendicular force on the side *AC* is to that on the back which balances it as *AC* is to *AH*; whence compounding these ratios, the oblique force against one side of the wedge is to the perpendicular force on the back which balances it, as *AC*² is to *AH* × *HC*. The oblique force *fe* on the other side of the wedge, being equal to *FE*, will require another perpendicular force on the back to balance it equal to the former perpendicular force; whence the whole force on both sides of the wedge is to the whole force on the back as *AC*² is to *AH* × *HC*; or as the square of the

side of the wedge to the rectangle under half the back and the perpendicular height.

For other methods of estimating the effect of the wedge in various cases, see *MECHANICAL Powers*.

The wedge is a very great mechanical power, since not only wood but even rocks can be split by it; which it would be impossible to effect by the lever, wheel and axle, or pulley; for the force of the blow or stroke, shakes the cohering parts, and thereby makes them separate the more easily.

To the wedge may be referred all edge-tools, and instruments which have a sharp point, in order to cut, cleave, slit, chop, pierce, bore, or the like; as knives, hatchets, swords, bodkins, &c.

WEDGE, in *Ship-Building*, a triangular solid made of wood or iron. It is one of the mechanic powers, the most simple, and of the greatest force.

WEDGE ISLAND, in *Geography*, a small island in the North Pacific ocean, near the E. coast of the Prince of Wales's Archipelago, in the Duke of Clarence's Strait. N. lat. 55° 8'. E. long. 228° 20'.

WEDGES, in *Agriculture*, are a sort of levers or distending powers that are of great use to the farmer on many occasions, as in tearing and splitting wood of all sorts, the roots of trees in taking them out of the ground, stones, and many other sorts of hard materials. About farm-houses of any extent, it is always of advantage to have a proper mallet and set of wedges for tearing up wood and other matters.

WEDGWOOD, *JOSIAS*, in *Biography*, was the younger son of a Staffordshire potter, and born in July 1730. His education was restricted, but his mental powers were of a superior kind, so that by the fixed and persevering exercise of them he made very considerable improvement in the art of pottery to which his attention was directed, and gave a name as well as reputation to the place of his nativity. (See *POTTERY* and *THE POTTERIES*.) His patrimony was small, but by his super-eminant skill and steady application he was the founder of his own fortune as well as fame. The principal feat of the potteries of Staffordshire was Burslem; and there is reason to believe that they have existed in or near this place for many centuries, and even, as some say, since the time of the Romans. But they had continued for a long time in the same rude state in which Plot found them when he surveyed this county. The merit of introducing into this country improvements in the art of pottery must be ascribed to two brothers of the name of Eders, who came hither from Holland about the year 1700, and settled in the neighbourhood of the Staffordshire potteries. They manufactured a red unglazed porcelain from a clay, which they found in the estate on which they settled, called "Bradwell;" but this was only the brown stone ware, in the composition of which no flint is used; but they made use of salt in glazing it: this salt, or muriate of soda, was thrown into the oven at a certain stage of the firing process, and the pieces of ware were so disposed as to receive the fumes of it on every part of their surfaces. The fumes, however, occasioned an alarm in the neighbourhood, which obliged them to leave the country. A similar manufactory, however, was soon after established at Shelton, in the Potteries, by one of their workmen, whose name was Astbury, and who had possessed himself of their secret; and as it was found very useful, it was tolerated by the inhabitants, though on the day of glazing, the dense offensive fumes from fifty or sixty manufactories filled the valleys, and covered the hills through an extent of several miles. The white stone ware,

and the use of ground flints in pottery, were introduced at a later period, and, as it is said, (see Parkes's Chem. Catechism,) in consequence of the following incident. About the year 1720, a potter, supposed to be the above-mentioned Astbury, stopped at Duntstable in his way to London, and sought a remedy for a disorder in his horse's eyes; and the oiler of the inn by burning a flint stone reduced it to a fine powder, which he blew into them. The potter, observing the beautiful white colour of the flint after calcination, instantly thought of applying the discovery to the improvement of his art, and afterwards introduced the white pipe-clays found on the south side of Devonshire, instead of the iron-clays of his own country, and thus produced the white stone ware. At first the flints were pulverized to the great injury of the persons employed; till the famous Brindley, in the early period of his life, constructed the mills that are now used for grinding them in a moist state. It is farther said, that an ingenious mechanic, named Alfager, afterwards improved the construction of the potter's wheel, so as to give much greater precision and neatness to the work. But still the French pottery exceeded in beauty that of Staffordshire; and about the year 1760, a considerable quantity of it was imported, and purchased by persons of opulence to the great detriment of the English manufacture. Mr. Wedgwood directed his attention to this article, and made several improvements with regard to the forms, colours, and composition of his manufacture; and in the year 1763 invented a kind of ware for the table, which gave a turn to the market, and under the name of queen's ware, conferred upon it in consequence of the patronage of her majesty, came into very general use. Its materials were the whitest clays from Devonshire and Dorsetshire, mixed with ground flint, and covered with a vitreous glaze. By varying and repeating his experiments, Mr. Wedgwood discovered the mode of manufacturing other species of earthenware and porcelain, excellent and beautiful, and adapted to various purposes both of use and ornament. With a view of prosecuting his improvement in pottery he applied to the study of chemistry, and for his farther assistance engaged the ingenious Mr. Chisholme, who had been employed in a similar department by the celebrated Dr. Lewis, author of the "Commercium Philosophico-Technicum;" for whom he not only built a comfortable habitation near the manufactory, but liberally afforded him an annuity for his support under the decays of age, which he continued till his death. Aided also by the classical taste of his partner, Mr. Bentley, potteries were furnished which served as models for various articles, formed of other materials, that were held in high estimation. We learn from Dr. Bancroft, that almost all the finely diversified colours which Mr. Wedgwood applied to his pottery were produced only by the oxyds of iron. In the manufacture of his beautiful jasper ware, which rivalled the productions of antiquity, and which found its way into the collections of the curious in all parts of Europe, he employed the native sulphate of barytes, and from this use of it he derived great profit, until by the infidelity of a servant the secret was disclosed and sold, so that others employed inferior workmen at a reduced salary, and thus prevented Mr. W. from employing his exquisite modellers on that branch of the manufacture.

Among other curious productions of this inventive manufacturer we may mention his imitation of the Barberini or Portland vase, which was discovered in the tomb of Alexander Severus, and for which the late dukes of Portland paid 1000 guineas. The subscription for Mr. W.'s manufacture was at the rate of 50*l.* each for fifty vases, but such were the expences of its execution, that the partners lost

money by the undertaking. Mr. Webber, it is said, received 500 guineas merely for modelling it. See VASE.

We cannot forbear in this connection noticing two cameos of Mr. Wedgwood's manufacture; one of a slave in chains, of which he distributed many hundreds, with a view of exciting the humane to assist in the abolition of the slave-trade; and the other a cameo of Hope, attended by Peace and Art and Labour, which was made of argillaceous earth from Botany Bay, to which place he sent many of them, in order to shew what their materials were capable of, and to encourage the industry of the inhabitants.

To this brief account of some of the numerous productions of Mr. Wedgwood, we shall subjoin the tribute paid to his industry and genius by an elegant modern poet:

"Gnomes! as you now dissect with hammers fine
The granite rock, the noduled flint calcine;
Grind with strong arm, the circling chertz betwixt,
Your pure kaolins and petuntzes mixt;
O'er each red faggar's burning cave preside,
The keen-eyed fire-nymphs blazing by your side;
And pleased on Wedgwood ray your partial smile,
A new Etruria decks Britannia's isle.
To call the pearly drops from Pity's eye;
Or stay Despair's disanimating sigh,
Whether, O Friend of Art! the gem you mould
Rich with new taste, with ancient virtue bold;
Form the poor fetter'd slave on bended knee
From Britain's sons imploring to be free;
Or with fair Hope the brightening scenes improve,
And cheer the dreary wastes of Sydney-cove;
Or bid Mortality rejoice and mourn
O'er the fine forms on Portland's mystic urn.
Whether, O Friend of Art! your gems derive
Fine forms from Greece, and fabled gods revive;
Or bid from modern life the portrait breathe,
And bind round Honour's brow the laurel wreath;
Buoyant shall sail, with Fame's historic page,
Each fair medallion o'er the wrecks of age;
Nor Time shall mar, nor Steel, nor Fire, nor Rust,
Touch the hard polish of the immortal bust."

The demand for Staffordshire ware very much increased, and it became a commercial article of exportation of very considerable value.

The district which Mr. Wedgwood inhabited became by his means the seat of population and abundance. The vicinity was enriched, and a new canal of importance, called the Grand Trunk canal, and connecting the Trent and the Mersey, was obtained and executed by his influence. The ample fortune which he acquired was liberally enjoyed, and benevolently applied to many purposes of private charity and public utility. Chemistry and the arts in their mutual connection were objects of his attention; and he contrived an instrument for measuring high degrees of heat, called a pyrometer, of which he gave an account in the *Phil. Transf.* for 1782, 1784, and 1786. See THERMOMETER.

The disposition and manners of Mr. Wedgwood were no less estimable than the powers of his mind; so that he was as much the object of admiration and esteem for his moral as for his intellectual qualities. So much was he respected, and so desirable was the continuance of his useful life, that he died, universally regretted, at his house in Staffordshire, to which he gave the name of Etruria, in January 1795, in the 65th year of his age. Aikin's Chem. Dict. Gent. Mag. Parkes's Chemical Catechism. Parkes's Essays.

WEDINOON, in *Geography*, a district of Suse in the southern division of Morocco, inhabited by a tribe of Arabs.

This territory is adjacent to the river Akassa, called by some Wed Noon, that is, the river of Noon. Jackson states the population of Wedinooon at 200,000 persons. In this district the sovereignty of the emperor of Morocco is scarcely acknowledged; and the difficulty of passing an army over that branch of the Atlas, which separates Sufe from Haha, secures to the Wedinooones their arrogated independence. Wedinooon is a kind of intermediate depot for merchandize on its way to Soudan, and for the produce of Soudan conveyed to Mogodor. Gums and wax are produced here in abundance; and the people, living in a state of independence, indulge in the luxuries of dress, and use many European commodities. A great quantity of gold dust is bought and sold at Wedinooon. The inhabitants sometimes trade to Mogodor, but prefer selling their merchandize on the spot, as they do not wish to trust their persons with property within the territory of the emperor of Morocco. With Tombuctoo they carry on a constant and advantageous trade, and many of the Arabs are immensely rich. They also supply the Moors of Morocco with (katas) convoys through the desert, in their travels to Tombuctoo. The coast of Wedinooon extends a long way to the southward, nearly as far as Cape Bojador. The river Akassa, commonly called the river of Non or Nun, and in some maps Daradus, is a large stream from the sea to the town of Noon, which is about fifteen miles inland, and about two miles in circumference: from hence the river becomes shallow and narrow; and it is to the southward of this river that ships are generally wrecked. The district of Wedinooon is nominally in the dominions of the emperor of Morocco; but lately an army having been sent farther south than Terodant, and the Pacha Alkaid Mahammed ben Delamy being dead, that district has suffered neglect, and the people pay no tenth, according to the mode of raising taxes in West Barbary, *viz.* ten *per cent.* on the produce of the land, and two *per cent.* on that of cattle; and the emperor has recently ordered his Pacha of Haha to purchase the British slaves that had been wrecked there. This place being only thus nominally in his dominions is another impediment to the redemption of the sailors who happen to be shipwrecked about Wedinooon; for if the emperor had the same authority over this district, that he has over the provinces north of the river Sufe, measures might be adopted by the consul, acting under his orders, for their delivery, without pecuniary disbursements. Jackson's Morocco. See VLED DE NUN.

WEDLOCK. See MARRIAGE, WIFE, HUSBAND, &c.

WEDNESBURY, in *Geography*, an ancient market-town in the south division of the hundred of Offlow, and county of Stafford, England, is situated at a short distance from the source of the river Tame; 19 miles S.S.E. from the county-town, and 125 miles N.W. from London. In the time of the Mercians, this place had a noble castle, which was fortified by Adelfleda, who was for some time governess of this extensive kingdom: but no part of the fortrefs now remains, except a few traces of its foundations. At the Norman Conquest, the manor became a portion of the royal demesnes. Henry II. bestowed it on the family of the Heronvilles, from whom it passed, after various successions, to the Beaumonts. The town is distinguished for its numerous and valuable manufactures, the principal of which are of guns, coach-harnes, iron axle-trees, saws, trowels, edge-tools, bridle-bits, stirrups, nails, hinges, screws, and cast-iron works of every description. For their proficiency in these various branches, the inhabitants are chiefly indebted to the abundance and excellence of the coal obtained in the immediate vicinity. This coal is indisputably the best in the kingdom for the smith's forge, on account of the intense

heat which it produces. It extends in a variety of separate veins or strata, which are particularized by the miners with the greatest accuracy. Here is also found that peculiar species of iron-ore denominated blond-metal, used in the manufacture of horse-shoes, hammers, axes, and heavy tools. Some spots likewise abound with a sort of reddish earth, called hip, employed in painting and glazing vessels of various kinds. A weekly market on Wednesday affords the town a plentiful supply of all kinds of provisions. The population of the parish, in the return of the year 1811, was stated to be 5372, the number of houses 1004. One of the collateral branches of the Birmingham canal, entering this parish, affords the inhabitants great facility of commercial communication. The church is an ancient structure, and some writers absurdly relate, that it was built in the year 711, by Dudo, lord of Dudley. At one end rises a tower, supporting a lofty spire: the interior is divided into a chancel, nave, and two aisles; the latter are separated from the nave by a range of arches, supported by octagonal pillars. In the chancel are several prebendal stalls, ornamented with exquisite carved work. Here is also a variety of monuments in honour of the ancestors of the Dudley and Harcourt families, and several other ancient tombs and memorials. Round the church-yard some vestiges of the castle may be distinctly traced.—Shaw's History of Staffordshire, folio, 1798. Beauties of England and Wales, vol. xiii. Staffordshire, 1811.

WEDNESDAY, the fourth day of the week, formerly consecrated by the inhabitants of the northern nations to Woden or Odin, who, being reputed the author of magic and inventor of all the arts, was thought to answer to the Mercury of the Greeks and Romans, in honour of whom they called the same day *dies Mercurii*.

WEDNESDAY, *Asb.* See ASH-Wednesday.

WEDNOCH, in *Geography*, a river of England, which joins the Wever, near Northwich, in Cheshire.

WEDUM, a town of Sweden, in West Gothland; 18 miles S. of Skara.

WEE-CHAUNG-HOO, an extensive lake of China, which divides the province of Shan-tung from that of Kiang-nan, and supplies an adjoining canal when it is deficient of water. This lake affords a charming prospect, particularly at sun-rise; when its borders fringed with wood-houses and pagodas on the sloping grounds behind, and the surface of the water almost covered with vessels crossing it in different directions, and by all the various modes of navigation that poles, paddles, oars, and sails, are exhibited to advantage. Fishing forms a considerable part of the occupation of the people on this lake, and they have various modes of conducting it. Besides nets, which are in most common use, they have another method, which is more singular: to one side of a boat a flat board, painted white, is fixed at an angle of about forty-five degrees, the edge inclining towards the water on moon-light nights; the boat is so placed that the painted board is turned to the moon, from whence the rays of light striking on the whitened surface give it the appearance of moving water, on which the fish being tempted to leap as on their element, the boatman raising with a string the board, turns the fish into the boat. Water-fowl are also taken upon this lake by a peculiar device. Empty jars or gourds are suffered to float upon the water; that such objects may become familiar to the birds; the fisherman then wades into the lake with one of the empty vessels on his head, and walks gently towards a bird, and lifting up his arm draws it down below the surface of the water, without disturbing or alarming the rest, and thus presently fills the bag with which he was provided for securing

ing his prey. A similar practice exists, as we learn from Alloo, among the nations of Carthage, upon the lake Ciengo de Terias. Staunton's Embassy, vol. ii.

WEED, in *Agriculture and Gardening*, any sort of uncultivated and unprofitable plant or vegetable which grows in ground, and which, in consequence of the mischief it does, requires to be extirpated and destroyed.

Weeds may be distinguished, according to the different periods of their duration, into the *annual*, *biennial*, and *perennial* kinds.

The first division comprehends all such as die after perfecting their seeds in the first year. Weeds of this class, though abundantly productive in seeds, and consequently in plants, are capable of being destroyed without any great difficulty.

The second division includes all such weeds as endure a greater length of time than one year, and which after perfecting their seeds in the second year perish. These, like the former, are in general abundant in the production of seeds as well as plants, but they are destroyed with greater difficulty.

The third division comprises all those weeds which are capable of continuing many years. Some of which have the property of perfecting their seeds annually, without being thereby destroyed; while others, less prolific in seeds, have the faculty of reproduction in their vivaceous roots; and there are others that are capable of increase both by seeds and roots. The plants of this class are therefore much more troublesome and difficult of destruction than the others.

In the nature and vegetation of the seeds of weeds of different sorts, there is considerable diversity. Some are found to sprout forth as soon as they have a sufficient degree of moisture, sending down their roots though not in exact contact with the earth; others only begin to germinate when they are deposited and inclosed in a suitable soil, and have the proper influence of the atmosphere; and there are many of these kinds of seeds, even of the very small sort, which are capable of remaining in a dormant or inactive state for a very considerable length of time, and afterwards vegetate on being placed in a favourable situation, in regard to the influence of the air, and other matters.

There are other seeds of weeds, too, which are provided with a soft feathery material which performs, in some measure, the office of wings, by which they are conveyed from their native situations, and disseminated over lands and places at a considerable distance.

There is likewise a difference of some consequence in the vivaceous roots of vegetable weeds; some being branched, others entire; some descending directly downwards, others inclining; some fibrous, others tuberous; some creeping, others knotted or jointed, &c.

The great variety and multiplicity of weeds render it a difficult matter to arrange them in any useful manner for the purposes of the farmer, as different sorts of them are found to prevail in different situations and kinds of land. A late intelligent writer has, however, considered them as affecting gardens; corn-fields and tillage-lands; meadows and pastures; waste and uncultivated grounds; the hedges of inclosures; and woods and plantations.

Weeds injurious to garden grounds are chiefly these:

Couch-grass, or which in some places is known by the names of twitch, squitch, and many others, and which not unfrequently comprehends the creeping roots of the hardy perennial grasses, which are particularly tenacious of growth, as dog's-grass, white bent-grass, tall oat-grass, and some others. Of which, the two first are readily distinguished

by their flowering stalks, as well as by the ears which contain the seeds; and the last has been observed to have a bulbous-jointed root, that affords shelter to various destructive grubs, worms, and insects: they should all be carefully rooted out and destroyed. These are to be destroyed in gardens by carefully picking out the roots in digging, and as carefully rooting up whatever remaining fragments of the roots may send out a shoot above the ground. These should never be allowed to get to any height, but be exterminated as soon as possible. See *TRITICUM Repens*, *AGROSTIS Alba*, *AVENA Elatior*, &c.

Suffolk-grass, or dwarf meadow-grass, is another grass, which, though useful in pastures, is a very pernicious weed in gardens and places about houses. It is common in places where the surface is not liable to be often disturbed by means of cultivation. Its prolific quality, in respect to seeds, is so great, that it is said to be capable of producing and reproducing itself four times in the course of one summer. It may be destroyed by rooting it out before its seeds are perfected and shed about, otherwise the vegetation of them will be so abundant and extensive as almost to bid defiance to the powers of the weeder. See *POA Annuua*, &c.

Catchweed, or what in different situations is called goose-grass, cleavers, hariff, &c. is sometimes a troublesome garden weed, but it is more common in the hedges. This is a weed that may be readily destroyed in garden-grounds, by pulling it up before the seeds are perfected.

It is said that young geese are very fond of the tender branches of this weed; and that the seeds of it are capable of being used instead of coffee. See *GALIUM Aparine*.

Garden nightshade is said to be a common weed in the garden-grounds about Chelsea and Brompton, but which is seldom found in those in the country, though sometimes met with on dung-hills, and other such places. See *SOLANUM Nigrum*.

Goosefoot, which is a weed of the wild orache description, is common and luxuriant in many garden-grounds, being very prolific in seeds, and in the produce of weeds therefrom, if not rooted out before the seeds are scattered about on land under cultivation. These, like all other annual seedling weeds, is to be destroyed only by rooting up before the seeds of it are scattered. See *CHENOPODIUM Album*, *Viride*, and *Hybridum*.

Wild orache, or fat-hen, is a weed nearly allied to the above, and from which it is distinguished only by some of the flowers having pointals only, while others on the same weed-plant have both chives and pointals, in common with the above sort of weeds. The flowers are small, so that this distinction can only be ascertained by the microscope. It is a weed which grows much in kitchen-gardens, on rubbish, and on dung-hills; is an hardy annual, very fertile in seeds; and which is to be prevented or destroyed in the same way as the above kinds. See *ATRIplex Hastata*.

Fools' parsley, or lesser hemlock, is a weed common in gardens, and which, in its early growth, has much resemblance to parsley, for which it is often mistaken, and when eaten occasions sickness, swelling, and uneasiness about the stomach: it should always be rooted out of garden-ground, when it is running to seed, as at that time it is easily known and best destroyed. See *ÆTHUSA Cynapium*.

Knot-grass is a weed that sometimes grows much on the gravel-walks of gardens and pleasure-grounds, trailing to a considerable length in all directions, being very prolific in seeds, which readily take root. It is, therefore, necessary to root it well up before they become ripe: hogs
are

are said to be very fond of eating it. See *POLYGONUM Aviculare*.

Ground-ash is said to be a very troublesome weed in the garden-grounds in the neighbourhood of London; but which some suppose to be mostly confined to the shade of hedges. It is believed to be perennial in its nature. In order to get rid of it, the best mode is to cut it up on its first appearance. See *ÆGOPIDIUM Podragaria*.

Chickweed is a weed that sometimes grows with great rapidity, and in a very luxuriant manner on garden-ground that is much pulverised and reduced by operose cultivation by the spade, and which is much enriched by good manure: it is an annual weed, very productive of seeds, and where it abounds much, it is perhaps improper to give the land or ground a fine culture until it in some measure disappears: swine are extremely fond of this weed, and it is said to be a grateful food for young chickens. See *ALSINE Media*.

Black-bind-weed in some places is called bear-bind. It is a parasitical weed-plant, often climbing up bean and other garden crops: it is hardy, and extremely prolific in seeds. To keep garden-ground clear of it, the seeds should never be suffered to shed or sow themselves: the seeds contain a white flower, and are said to be good for pigeons, poultry, and small birds of different kinds. See *POLYGONUM Convolvulus*.

Sun spurge is an annual weed, said to be not very troublesome or difficult of eradication, yet not uncommon in garden-grounds. See *EUPHORBIA Helioscopia*, &c.

Red dead nettle, or dee nettle, is a weed of the annual kind, according to some, but which others consider as a perennial. It is common in garden-grounds, flowering early, and for the greater part of the year. The seeds should not be suffered to shed or disperse themselves over the ground, but the weeds be cut up as soon as they appear. See *LAMIUM Purpureum*.

Henbit is an annual garden-weed, that should likewise be weeded out before the seeds of it are perfected and scattered. See *LAMIUM Amplexicaule*.

Nettle hemp is a weed of the luxuriant, disagreeable, garden kind, that should always be rooted out of the ground, and kept under in time to prevent its future mischief. See *GALEOPSIS Tetrabit*.

Garden sow-thistle is a common weed of luxuriant growth, doing great injury to the cultivated crops. It is directed that the seeds of this weed should never be suffered to shed and spread themselves in any situation; for, being furnished with feathers, they fly over a country with the wind, disseminating themselves widely, and vegetate on the first loose or cultivated ground on which they settle. It is a favourite food with rabbits and hogs. See *SONCHUS Oleraceus*, and *THISTLE*.

Fumitory is a common, though not very injurious or hurtful weed. It is an annual, and may, consequently, be destroyed by preventing its seeding in an effectual manner. See *FUMARIA Officialis*.

Common thistle is a disagreeable and troublesome weed; the seeds of which are numerous, and provided with a downy material to carry them any distance before the wind. They should be drawn up by the roots in moist weather with forceps or tongs for the purpose, as they cannot be pulled by the naked hand.

Garden-grounds are always to be kept well freed from weeds of this sort by all proper means. See *SERRATULA Arvensis*, and *THISTLE*.

Groundsel, which is another very common and troublesome weed in garden-grounds, and the seeds of which are

feathered, as in the former case, being capable of sowing and spreading themselves far and near, with this farther chance of propagating themselves, that the plant or weed is extremely quick of growth. The eradication of this weed from gardens must consequently require unremitting attention, by cutting up the young plants as soon as ever they can be discovered, and letting them run to seed as little as possible. See *SENECIO Vulgaris*.

Common nettle is a weed that generally grows in hedges or other shady places, but which sometimes appears in other places and in garden-grounds; in which cases, it must be destroyed by rooting it up in a complete manner. The leaves of this weed, when cut small, may, it is said by some, be mixed with the food of turkeys, and other poultry, with benefit. See *URTICA Dioica*.

Mistletoe may be ranked as a garden-weed, and is very common on fruit-trees, and it is said to be very hurtful in preventing their bearing; it should, of course, be pulled off in time, so as to prevent that sort of injury. It is sometimes, too, plucked off as a sheep-food in the winter, in hard stormy seasons. See *VISCUM Album*.

Cultivated early potatoe, though it cannot be properly ranked as a weed, is often troublesome in gardens. It is said, that however valuable as a crop, it is very apt to remain in the ground, and intrude itself among other after-crops, to their injury, as well as giving a slovenly appearance to the culture. As, however, it is now found that the shoots of this root will crop well after being transplanted, it would seem to be the best way to have them taken up from among other crops as they appear, taking the advantage of showery weather, and putting them into a bed by themselves, where they may succeed some early crop, such as winter greens, spinach, forward cabbage, and such like, by which means other crops may be rendered clean, and these roots be provided without any expence of seed or sets. See *SOLANUM Tuberosum*, and *TRANSPLANTING*.

Weeds injurious in Tillage and Corn Lands.—The principal of those weeds which decidedly infest and injure grounds under the plough are those given below.

Ivy-leaved chickweed is a weed that is said sometimes to abound very much amongst wheat very early in the spring, but that as seeding and leaving the ground early, may perhaps not much injure the crop: the seed is asserted to ripen in twenty-eight days from the first vegetation of it and the springing up of the plant, which mostly appears in the month of March, and often sends forth a plentiful produce of seeds, which will lie in the ground many years, ready to vegetate the next time the land is broken down and pulverized early in the spring: this sort of work should, therefore, in this case, be done in the fallow, where that practice is in use, which would occasion the seeds to vegetate; but in other cases it may be destroyed by being ploughed under before the seeds of it begin to ripen. See *VERONICA Hederaifolia*.

Lamb's lettuce, or corn-fallad, is a weed that has lately been observed to be more frequent in some districts than formerly. It has been found in a hard tilled field in great abundance. It is an annual weed; and, though not very formidable, ought to be removed from tillage-lands, as it takes away a portion of the nourishment belonging to the cultivated crops. This may pretty readily be done by pulling or cutting it up, or turning it under by the plough, where it can be used, before the seeds of it be perfectly formed. See *VALERIANA Locusta*.

Couch of tillage-land is the produce of the three grasses already noticed in a similar title, under the head of garden-weeds, with the addition of the roots of the creeping soft grass,

grafs, and probably some others. It is said to be the plague of arable cultivation; and that the roots of these weeds are sometimes so interwoven together in the land or soil in ground that has been under hard tillage and bad management, as to form a perfect matting, and to choak the plough: they abound most, it is observed, in light and mixed soils, not infesting strong clays in an equal manner. The arable land squitch-grafs, which is the most general, is, it is said, of the *agrostis* family; but to which particular species or sort that the most complained of by farmers belongs, is not yet well agreed upon. Some refer it to the fine bent, while others assert it to be a variety of the white. And there are others of great authority who think this squitch-grafs has never yet been rightly specified or referred. The ear or awn of this grafs has, however, been often observed to have the general habit of the *agrostis*; and that it is very probable that more species than one of this genus have the property of running in the roots, and producing couch.

It is noticed, in addition, that the creeping red-stalked bent grafs, and the creeping soft grafs, are common squitch or couch-grasses on strong or cold wet tillage-lands; and that the tall oat-grafs is a very usual squitch-grafs, on the light gravelly soils of some neighbourhoods; that its roots are composed of a bunch of bulbs, which afford shelter to pernicious vermin, as already seen; and that it is difficult of eradication, and very pernicious to crops, especially in wet seasons.

The *dog-grafs couch*, which, in the county of Salop, is often termed *scutch*, is very common every where, and well-known to the cost of the farmers.

Withering, after observing that it can only be destroyed by fallowing in a dry summer, states, that at Naples the roots are collected in quantity, and disposed of in the market to feed horses. The taste is much similar to that of liquorice, dried and ground into meal, which has been made into bread in years of scarcity. They have besides a detergent quality, and may be useful in the diseased livers of animals.

However, these grasses, though so troublesome and injurious as weeds on arable lands, are yet probably good as affording meadow-herbage, where their roots are not so liable to run or spread themselves as on tillage-land that is loosened, broken, and reduced, by being constantly wrought by the plough, and other tools.

The destruction of weeds of this sort on arable land, is chiefly effected by the free use of the plough, and other suitable implements, when the weather is in a proper state of heat for the purpose: some think the business can only be effected by giving an early and complete spring and summer fallow, by repeated ploughings in time of hot weather, with sufficient harrowings between each ploughing, to work out the squitch, and bring it to the top; and that unless the summer prove dry for some length of time, even this will be insufficient; in which case, many active and industrious farmers have it forked together by hand and burnt: others have it collected and carried into heaps to rot; and it is sometimes mixed with quick-lime, and reduced into a sort of compost heap, which is a practice to be much commended, as wholly destroying it, and at the same time converting it to use: it should not, however, be forgot, that the great increase of the roots of these weeds is occasioned by hard tillage, or bad management, and often by both. In the county of Gloucester, it is said by the writer of the corrected account of the agriculture of that district, to be a most troublesome and almost unconquerable weed on clay-lands, but that on light lands and loams it

may be dragged out and finished by hand-picking with tolerable ease; while on the stiff soils, and particularly in the wet furrows, nothing but repeated ploughings and exposure to the heat of the sun during the summer can check the increase of it; hence, in that county, the vale-lands, after a wet summer, are generally foul. A crop of spring-vetches is said to be well suited to smother and keep it down, and other smothering green crops may be had recourse to in the same intention. See *TRITICUM Repens*, &c. Also *AGROSTIS Stolonifera*, *HOLCUS Mollis*, &c.

Wild oat, or *laver*, is a common weed on hard tilled land, and when abundant, very unsightly and injurious to a crop. It has been observed by Dr. Anderson, it is said, that this weed-plant abounds so much in the corn-fields in most parts of Aberdeenshire, as in many cases to constitute nearly one-half of the bear or six-rowed barley-crop, which is much grown in that part of the kingdom: it may be destroyed or greatly reduced by the turnip-culture, or by well-managed early fallowing; and prevented by short tillages, and frequent seeding down to grafs. Dr. Withering, and the *Flora Rustica*, have stated, that the awns of it are used for hygrometers, and the seeds instead of artificial flies in fishing for trout. The author of the Corrected Report of the Agriculture of the County of Gloucester states, that it is the growth of particular districts, and that it cannot be destroyed; that in fields where the greatest care has been taken to hand-pull every stalk, it has appeared in the following year in equal abundance. That in new broken up leys, which have been in turf or sward beyond the memory of man, these weeds often spring up with as much luxuriance as if they were the natural produce of the soil. When the land is planted with beans or peas, hoeing will check and reduce them; but when they grow among wheat, it is not easy to distinguish the plants while young; and that in this case, they are left until they are nearly in ear, and are then drawn out by the hand. See *AVENA Fatua*.

White darnel is a weed not unfrequently found in wheat-crops, though, it is believed, almost always produced from the seed of it sown with that grain, to prevent which, consequently, great attention should be paid to clean seed-wheat, and particularly that it contain none of the seeds of this weed, as it is extremely prolific, very injurious to a crop while growing, and to the value of the produce at market. It is an annual weed, which has never been recollected to have been seen growing, except in a crop, and but rarely there without neglect in the management of the seed grain, and in other ways. See *LOLIUM Temulentum*.

Goose-grafs, or *catchweed*, &c. is a weed in tillage-land, the seeds of which are roundish, rough, two from each flower, so large as not all to be easily separated from the grain in dressing. This weed is not very common in well-managed lands and crops, being more generally restricted to the hedge banks. It is observed, in the Gloucester Corrected Agricultural Survey, to be a troublesome and frequent weed, on all sorts of soils among corn, and which is not easily destroyed, except by much early care and attention. See *GALIUM Aparine*, and *Spurium*.

Field scabius is a weed found sometimes in corn-fields, as well as pastures, though not very abundant. See *SCABIOSA Arvensis*.

Parsley-piert is a diminutive weed of but small account, though sometimes too much abounding in tillage-lands. This weed might probably be weakened and lessened when in too great quantity by pulverising and reducing the soil well when in fallow, very early in the spring season, and by
ploughing

WEED.

ploughing it under in due time, so as to prevent its seeding. See *APIANES Arvensis*.

Dodder is a parasitical weed, that is said not to be uncommon, in some districts, in the corn-lands. This weed has been observed twining round the stems or stalks of a bean crop in the county of Buckingham, climbing in a spiral direction round them, from which, by means of vessels for the purpose, it draws its nourishment and support, and must, consequently, very much fret and injure any plant to which it may attach itself: it is called in different places, as stated by writers on husbandry, beggar's-weed, hell-weed, and devil's guts, names which sufficiently shew in what sort of estimation it is held by farmers. It is an annual weed, and produced from seed, which takes no root in the earth, but in some part of its foster-plant. It is remarked, by the author of the Corrected Report on Agriculture for the County of Gloucester, to be a great enemy to beans, vetches, and some other such plants, but is never there seen among wheat, barley, or oat-crops. That as soon as it has fixed itself upon the plant, it separates from the root, and, like other parasitical weeds, draws all its nourishment from the plant it has so fixed upon and embraced. Large quantities of beans are, it is said, often ruined completely by it, so as not to carry a single pod; and that no method has yet been discovered to destroy it; for though the root cannot be found, yet it surely returns, it is thought, in some part of the field where it has once begun to grow, whenever the plants on which it feeds, form the crop of the season. Sheep, in some cases, have been found useful in lessening it, by feeding upon it and breaking its runners, when they can be turned into the land where it prevails. See *CUSCUTA Europea*.

Corn bind-weed is another troublesome parasitical weed in arable-land, often growing amongst wheat, and, when abundant, twining round the stalks of the corn, and very much injuring the crop, when the wheat has been laid by heavy rain. It is said not to be so common in some of the midland counties, as in some of those nearer the metropolis, whence they are in the habit of procuring and being supplied with seed-wheat; on which account it has sometimes been feared that it might be introduced more abundantly by such means: but as the seeds are small, they may easily be dressed out in case of such accidents. It is a perennial weed, and much addicted to running in the root. It has been proved by an experienced writer, that cutting it off, even below the surface of the ground, only tends to spread it farther: it must be reduced and destroyed, if possible, by means of fallowing, and using the same process as for couch or squitch. In some districts this weed is most frequently found in clays and deep loams, in which the roots strike so low, that even trenching two spits and an half deep will not, it is said, reach their extremities; and that the smallest bit of a root left in the ground will spring and rise to the surface. It entwines round and entangles all plants in such a manner, as either to bring them to the ground, or check their vegetation, by injuring their structure on the surface of it. See *CONVOLVULUS Arvensis*.

Wild carrot is a common and sometimes a troublesome weed, in dry tillage-land. It is a biennial weed-plant, producing seed in a plentiful manner. Though some, as Withering, assert that this, in its cultivated state, is the common well-known garden carrot; yet others, as Miller, contend that the wild carrot could never be improved so as to render the roots in any degree comparable with the cultivated carrot. However this may be, where it is found in quantity, it should be prevented from seeding, in order to reduce it, and bring it properly under, which may be ef-

fectured by cutting or pulling it up in its early growth. See *DAUCUS Carota*.

Shepherd's needle, or beggar's needle, is a weed sometimes abounding in hard tilled land, and the seeds of which are not wholly separable with ease from grain in dressing. It is a small annual weed, that produces a plentiful crop of seeds, each seed being furnished with a spike or beak of from one to two inches long, whence its name of needle. It seldom abounds much in well cultivated and managed land. See *SCANDIX Pecten*.

Chickweed is, in some cases, a troublesome weed in a crop on land which has been rendered fine by tillage, and from which it should, therefore, be rooted out. It has been remarked by the Rev. Mr. Shaw, it is said, that this weed is an excellent out-of-door barometer:—that when the flower expands boldly and fully, no rain will happen for four hours or upwards; that if it continue in that open state, no rain will disturb the summer's day; that when it half conceals its miniature flower, the day is generally showery; but that when it entirely shuts up, or veils the white flower with its green mantle, let the traveller put on his great coat, and the ploughman with his beasts of draught rest and retire from their labour. In Gloucestershire it is stated that it grows most plentifully on the good and well cultivated lands. It there mats so closely round the plants, and covers the surface so completely, as to keep out the influence of the sun and air; and consequently requires to be removed, which is most best performed by the hoe. It may be thus kept under, if not wholly removed and destroyed. See *ALSINE Media*.

Curled dock is a mischievous weed in tillage-land, and should never be suffered on any account to seed its seeds, and spread them on any land, but be rooted up and carried off in time, to prevent injury. In arable ground, the roots are best picked off with care during the time the land is in tillage, as they will otherwise produce vigorous luxuriant plants which will draw much nourishment from the soil, to the great injury of the ground, and of the intended crop. It is a hardy perennial weed, which is very tenacious of growth by its roots, and producing a wonderful increase of seeds: too much caution cannot, therefore, be used to avoid sowing it, nor too much pains be bestowed in its extirpation and destruction. Withering asserts it to be the pest of clover-fields in Norfolk. See *RUMEX Crispus*.

Arsenaris, or lake weeds, are plants of this kind, sometimes met with on the wetter sorts of arable lands. They abound most in wet seasons, on the heavier and more moist sorts of ground; and as being hardy annuals, producing a plentiful supply of seeds, are apt to shew themselves in the crops of grain. They are weeds which are to be destroyed by proper fallowing, by the removing of the wetness of the land, and by the rooting out of the plants in proper time to prevent their seeding. See *POLYGONUM Persicaria*, and *Pensylvanicum*.

Knot grass is sometimes a tillage-weed; trailing in its habit of growth; flourishing most by the way-sides: when out of the smothering crops, it is very prolific in seeds. It should be got under by preventing its seeding, by rooting it out sufficiently early for the purpose. See *POLYGONUM Aviculare*.

Bearbind, or black bindweed, is a parasitical weed that twines round any thing it can lay hold of, and which is sometimes found among field crops, to their great injury. It is very productive of seeds, which, being angular, are not easily separated from grain in dressing or winnowing it. It is nearly allied, it is said, to buck-wheat, and to which it is preferred by Dr. Withering, who asserts that the seeds are

are quite as good for use as those of that wheat, are produced in greater quantity, and the plant bears cold better. From its twining hurtful nature, when among crops, it should be early destroyed, and prevented from feeding and multiplying itself. See *POLYGONUM Convolvulus*, and *Sagopyrum*.

Knawell is a diminutive weed, but prolific in seeds, and of vigorous growth; it is often found on pieces of poor thin soil, when in tillage, but is not believed to be very pernicious: it may probably, when necessary, be weakened, reduced, or destroyed, by an early spring working of the land when in fallow. See *SCLERANTHUS Annuus*, and *Perennis*.

Bladder campion is a weed that is common in wheat and barley crops, growing in tufts, with many stalks from each root; which, when the case, should be rooted out by the hand, or other convenient method. It is a perennial weed, and has the habit and property of increasing from the roots. See *CUCUBALUS Behen*.

Cockle is a luxuriant, vigorous, annual weed; perfecting many seeds, and drawing much from the soil or land: care should, therefore, be taken not to sow the seed of this injurious weed. The seeds are so large, that they cannot all be dressed out from the grain, it is said: the plant should, therefore, be plucked out by hand, before the seeds ripen and shed themselves. It is a common weed among wheat and other crops, in many districts. See *AGROSTEMMA Githago*.

Red and white campion are weeds of the perennial kind, growing occasionally in hedges, corn-fields, and pastures. When they become abundant and injurious, they may be weakened, reduced, or destroyed, by well-managed fallows, in most cases. See *LYCHNIS Dioica*.

Moufe-ear is a weed that has somewhat the habit of chickweed, but is of a duller appearance: it is frequent amongst corn-crops, and in pastures, but perhaps not very injurious to the former. See *CERASTIUM Arvense*.

Corn spurry, or yarr, is a frequent weed in corn-fields, though not very bulky or luxuriant, yet quick and tenacious of growth, and producing seeds in a plentiful manner. Dr. Anderson has stated, that in Aberdeenshire it is a pernicious weed, growing in such abundance among the crops as to choke the grain: it has often been seen so thick, that over a vast extent of surface a pin could not have been put down, without touching a plant of it; and that the farmers there think it indestructible: and it is added, that whenever any of the land had been poached, by being used as a road, especially in wet weather, none of this weed appeared there: that it was evident that this was occasioned by the clods, thus produced, not giving room for the small seeds to germinate freely; which suggested, that if, therefore, he could contrive to bring the ground into a cloddy state, when sown, he should be free of the weed for that crop. As a crop of bear or six-rowed barley in one field was entirely lost, the soil or mould being in a loose, mealy, incoherent state when sown; it was resolved to delay ploughing it the next season as long as possible, and to plough it at last when it was very wet. Fortunately it came a violent rain in the beginning of the month of March, and it was ploughed when nearly in the state of a puddle, turning over more like mud than soil or earth: dry weather succeeding, this mud bound, it is said, a little on the surface, and produced a kind of clod; the corn was then sown; it got a very slight harrowing, barely to cover the seeds, in an imperfect manner, and to leave the field as rough as possible: none of the weed appeared, and the crop at harvest was one of the most luxuriant that had ever been seen by the writer. The suc-

cess of this case is not, however, sufficient to recommend it as a general practice.

It has been suggested, that as small birds are very fond of the seeds of this weed, it is probable that, by the surface of the ground being left undisturbed through the winter, a large portion of the seeds would be picked up and devoured by them. It is believed too, that in all cases of a stubble very full of small seeds, it is well to defer the ploughing as long as it conveniently can, on this account. In respect to land rendered very fine by tillage, it is well understood, it is said, by the farmers of some districts, as those of Staffordshire, to be a fault, and that it is much better left only knappy, as they call it, that is, in small lumps. This is attained in fallows, by working the land early in summer, and letting it lie to consolidate through the latter part of it; and in the turnip culture, by the treading of sheep and cattle: and it is one great reason, it is supposed, why land should not have too many ploughings, but only a proper number judiciously timed; however, that ploughing in general, particularly of broken land, is much best done when the land is dry.

By some means of this kind, this small weed may be kept under without much difficulty. See *SPERGULA Arvensis*.

Base rocket is a weed of the annual kind, that does not abound very much, though it is met with in some places. It has been observed among corn in the county of Gloucester. See *RESEDA Lutea*.

Dwarf spurge is a weed that is common in corn-fields, and generally in single plants, but is not very injurious to the crops. See *EUPHORBIA Exigua*.

Corn-poppy is an annual weed that produces numerous seeds, and is sometimes very abundant in corn-fields, being a pretty sure indication of a light crop. It has been questioned, whether the lightness of the crop be occasioned by the abundance of this weed, or the increase of this weed encouraged by the lightness of the crop; and suggested, that probably both are the case. In a full crop it is scarcely to be found; its flowers appear in July. In the Corrected Report on Agriculture for the County of Gloucester, it is stated to be common in all light and sandy soils, particularly in the neighbourhood of that town. But that since the practice of hoeing has become more general, this weed has been much diminished in quantity. It abounds much, too, on chalky stone-brash poor soils, in some cases. And in some parts of Berkshire, it is said, in the account of its agriculture, that the poppy almost conceals the corn, when it is in blossom. It is supposed that it might without doubt be weakened, reduced, or wholly destroyed, in fallows, by promoting an early vegetation in common with other feeding plants. See *PAPAVER Rheus*.

Corn crowfoot is a weed that is sometimes very abundant, and injurious to a wheat-crop, on strong moist land. It is an annual weed of early growth, which can only be brought into a full state of vegetation in the fallow by an early tillage; otherwise the growth of the seeds is, it is said, deferred to the next spring, to the great injury of the crop. In the Flora Rustica it is noticed, that in some countries it has the name of hunger-weed, whence it is supposed to indicate a barren soil. The orthography, however, is not, it is said, derived from the nature of the soil, but from the hungry prospect it holds out to the farmer. In the county of Gloucester, it is said to grow most abundantly in strong loamy or clayey soils; and that deep and frequent stirrings with the hoe are to be had recourse to, as the most proper means for reducing it, and keeping it under. See *RANUNCULUS Arvensis*.

Dec nettle, or dead nettle, is a weed that much abounds among

WEED.

among tillage-crops, on some lands, especially in moist seasons. As the weeds are perennial, and produced both from seeds and the roots, great pains are necessary to be used in their extirpation and destruction. There are sometimes different sorts met with among crops. See *LAMUM Album*, and *Purpureum*.

Calves' snout is a weed in tillage-lands, in different districts. It has been observed not to be uncommon among the corn-crops in Hampshire, in some summers. It would appear too from Withering, that several other species of this genus are common in corn-fields, which are annuals; but the nature of them, or how far they are injurious to cultivated corn-crops, has not yet been determined. See *ANTIRRHINUM Orontium*, *Elatine*, *Spurium*, *Arvense*, and *Minus*.

Shepherd's purse, or pouch, which, with some others, are well-known weeds, are sometimes troublesome on arable land. They are annuals of early appearance, and continue a great part of the year. They are to be reduced and destroyed by early and well-directed fallowing, or by being rooted up from the ground at an early period. See *THLASPI Arvense*, *Campetere*, and *Bursa Pastoris*.

Whitlow grass is said to be a weed among corn, in some cases and sorts of land, early in the spring; but how far injurious is not well ascertained: it should, however, when in quantity, be kept well under. It is but small, though quick in growth, and exhausted in a short time. See *DRABA Verna*.

Coddled mouse-ear is another diminutive weed, that shews itself early sometimes among corn in tillage-lands; but being rapid in its vegetation and decline, is not of much importance as a weed to farmers.

Smooth and rough-leaved and pale-flowered chadlocks, &c. are weeds that are extremely troublesome and distressing to farmers on tillage-lands, in some places. The writer of the paper on weeds alluded to above has stated, that these three plants are sometimes confounded together by farmers, under the general name of chadlock, pronounced in the district where he lives kedlock, and in some others ketlock, though they are as distinct to the investigating inquirer as wheat, barley, and oats. That they are all extremely common, or nearly equally so, if a large range of country be examined; though the different sorts are more or less abounding in different places; that in his neighbourhood he can generally gather the three kinds in the same field, but the mullard is much the most abundant. In the vicinity of Litchfield, where chadlock is indeed very abundant, it is almost universally wild rape. Some years ago, the writer observed, in the common fields of the county of Rutland, that the whole surface was tinged over with the flowers of the wild radish. They are all great nuisances, and, when suffered in abundance to ripen their seeds, must of necessity draw much from the soil, to the great injury of the crop among which they are; and that as they are very quick of growth, and perfect their seeds expeditiously, it is not uncommon for these weeds to shed their seeds at the rate of several bushels on the acre; and as it is well known that the seeds are capable of vegetating, after lying many years in the ground, it is no wonder they should produce a plentiful crop; yet, being simply annuals, they are not difficult of destruction, if due attention and proper means be used. In order to destroy these, as well as all other seedling weeds, the land in tillage should, it is thought, be pulverised and reduced early in the spring by ploughing and harrowing, after which warm weather and rain will soon cause all the seeds that are near the surface to vegetate; they may then be permitted to grow until they begin to flower, when they

are to be ploughed in, and the land again harrowed; and the next rain will then cause most of the remaining seeds to shoot, which are in due time to be ploughed under as before; and if any should afterwards appear amongst the crop, they should be hoed or hand-weeded out: by this means, in one or two tillages, these weeds may be totally eradicated; but if they be permitted to shed their seeds, their increase cannot be wondered at, when their prolific nature is considered, as well as the extreme hardness of their seeds. The seeds, when dressed from grain, have, it is understood, been frequently manufactured into oil.

The weed called charlock, in many places, is said to be the most common of any in the vale of the county of Gloucester. It is most probably the same with the wild mustard, just noticed. It is said, that during the summer, both on the fallows and in the planted fields, its yellow blossoms predominate over every other plant, and that unless destroyed in this state, leave an immense crop of seeds behind. In order to check the increase of this weed, the attentive farmer suffers it to come into blossom on the fallows, and then turns it in with the plough. This is not always, however, effectual; as frequently the plants being merely moved, but not from the roots, and two or three inches of the tops left above ground, soon recover the injury they have sustained, and go on to seed before the next ploughing. Women and children should, therefore, go over the ground with the hoe a few days after the ploughing, and cut up the reviving plants; or lambs should be kept on such fallows, which are said to eat off the tops with avidity. In the planted fields they are hoed and weeded, but as some will unavoidably escape, women are put in among the corn, after it is grown to a considerable height, to pull out the weeds in blossom with the hand. Though the farmer will certainly diminish the quantity, and prevent any new accession by this attention, yet many years of good husbandry must elapse, before the ill effects arising from the negligence of former cultivators can be conquered; for the seeds being strongly charged with essential oil, will continue in the ground for an incalculable length of time uninjured; and as often as the soil is turned up, a quantity of them will be brought sufficiently within the influence of the atmosphere to vegetate. In 1804, in the parish of Brockthorpe, in the above county, a considerable portion of the land in the common field was seen completely covered with this weed, and the seeds perfectly ripe and scattering on the ground. The ploughing had been neglected until nearly the autumn, and as the land was not cropped, the charlock grew in great abundance, and left more seeds than the good husbandry of half a century will be able to eradicate.

It has been stated, that what is vulgarly called charlock in the vale of the above district, is in reality the common wild mustard grown in the north for its flour. That it is there often collected by the country-people for the same purpose; and before the simple mode of living among the ancient farmers fell into disuse, few farm-houses were without a cannon-ball and bowl, in which the mustard-seeds were bruised, and the flour saved for the table with the black hulks unseparated from it.

The name charlock is not unusually applied by farmers to different plants of the weed kind, that are equally noxious and hurtful in arable lands, and some of them perhaps more frequent in such situations than some of the above, such as wild mustard and rape, &c. See *BRASSICA Napus*, *SINAPIS Arvensis et Nigra*, *RAPHANUS Raphanistrum*, &c.

Wild rocket is a weed found in tillage-lands in some districts. It is said, that this weed has made great progress in the corn-fields in some places, and is considered as a very formidable

formidable and hurtful plant of that kind. All the parts of this are considerably acrid, and have a rank disagreeable smell; whence it is called by those farmers who have it in their lands *stinkweed*. It may, it is supposed, doubtless, be reduced and destroyed by the processes already recommended for the destruction of chadlock. See *BRASSICA Muralis*.

Fumitory is an annual weed, that is not uncommon or unusual in corn-fields, though not very greatly pernicious in them. It should, however, be kept well under where it is in any quantity. See *FUMARIA Officinalis*.

Rest harrows are weeds sometimes met with in tillage-lands. They are chiefly two sorts, the former of which is said not to be uncommon in arable lands, where there are no very desirable plants. It is common in some districts among corn-crops, and an hardy perennial weed. In its destruction, if the root can be got rid of in the fallow, there is little danger, it is said, from the seeds: the roots are sometimes so strong as almost to stop the plough, unless the team be pretty strong. The latter is frequently met with in some places, but is unknown in some of the midland counties. See *ONONIS Arvensis*, or *Spinosa*.

Tare, particularly in the wild state, is a weed very injurious to corn-crops. It is said to be a terrible enemy to a wheat-crop, where it abounds in considerable quantity. Withering says, that in wet seasons whole fields of corn have been overpowered and wholly destroyed by it. Care should be taken, that seed-wheat be perfectly free from the seeds of tares; and all land subject to them should be got, if possible, so forward in the fallow, as to bring on the vegetation of this weed previously to the sowing of the wheat: the seeds of this weed are said to be good food for pigeons, poultry, and many other sorts of birds. See *ERVUM Tetraspermum*, and *Hirsutum*.

Rape, in some cases, is a very injurious weed in arable land. It should, in all cases where it prevails much, be prevented from ripening and shedding its seeds, as when this is not the case, the farmer has long to regret the consequence of his neglect. See *Chadlock supra*.

Melilot is a weed very troublesome in tillage-land. The writer of the paper already noticed says, that it is a very injurious corn-weed in many parts of the kingdom. That Miller marks Cambridgeshire, and Gerard, Essex, as abounding in it. That it has been heard of in Bedfordshire, and seen among corn in Gloucestershire and Rutlandshire: that in the latter county, five or six shillings the acre have sometimes been said to be expended in weeding it out, without fully effecting the purpose. According to the *Flora Rustica*, there cannot be a worse weed among bread corn, for a few of the seeds ground with it spoil the flour, by communicating their peculiarly strong taste to it. That it flowers in June and the following month, and the seeds ripen with the corn; and that it is probably capable of propagating itself, both by its roots and seeds, but might doubtless be much weakened and reduced by proper fallowing: that horses are very fond of it; cows, sheep, and swine, eat it; and bees are very fond of the flowers: it is, therefore, though a corn-weed, a good pasture plant. It is said to be common in the vale part of the county of Gloucester, in the arable lands; and it has been suggested, that if the seeds did not afford an unpleasant taste to the flour of wheat with which it may happen to be mixed, it might probably be cultivated with advantage, as all domestic animals are fond of it in some degree. See *TRIFOLIUM Melilotus officinalis*.

Sow-thistle is a very common and troublesome weed in tillage-land: it is a perennial, and common among corn-crops in some districts; which, in all cases, when it happens to be so abundant, should be drawn up by the hand or other

proper means before it ripens and spreads its seeds; which, as being furnished with a feathery down, would otherwise fly over the whole country and district, as has already been seen. See *SONCHUS Arvensis*, and *THISTLE*.

Common thistle, cursed thistle, or sow-wort, is, in many cases, a troublesome and disagreeable weed in and about corn-lands and crops. It is commonly called thistle, growing almost every where: when injurious in corn-crops, it may, it is said, be weakened and reduced by good tillage and weeding, but not totally destroyed, in perhaps these or any other ways, otherwise than by universal agreement to root it up, before its seeds ripen and become spread, or by some regulation of police enforcing the same. This mischievous weed is produced by its numerous fibrous roots, which are hardy and strictly perennial, and which if separated in parts or pieces in ploughing, digging, or working the land, each part will, when left fresh in the soil, often grow or vegetate, and produce a new plant; and by its still more numerous seeds which are feathered, will fly and be carried to a great distance by the wind; and when it becomes calm alighting upon cultivated land, will there vegetate and rise luxuriantly, so that it would be in vain for any person to attempt clearing his land of this weed, unless his neighbours did the same likewise: however, the roots of this weed may, it is said, be pretty effectually destroyed by a well-managed summer-fallow, as they will not survive repeated ploughings up in hot weather; and if due attention were bestowed to prevent the seeding of the weed, its numbers might be diminished very greatly: it is found very hurtful to all field-crops. Some think it easily conquered, however, by proper management and attention in tillage-lands, and that it may either be drawn by the tool for that purpose, or be cut off deep by the hoe or speed-hook.

It is supposed, on the authority of the *Flora Rustica*, that the goat and the ass will eat it; that horses will sometimes crop the heads while young and tender; but that no other sort of cattle touch it growing. That when burnt, it is said to yield a very pure vegetable alkali. See *SERRATULA* and *THISTLE*.

Spear, bur, or boar thistles, are weeds of a very pernicious nature in corn-lands, in many instances and parts of the kingdom. They are said to be called by the last of these names in Staffordshire, to distinguish them from the above weeds, which are likewise termed thistles. There are several sorts of them, and they often abound about the hedge-sides and borders of corn-fields, whence they should be rooted up after rain as much as possible, before their seeds ripen and are ready to spread, otherwise such seeds are liable to fly all over the country, as has been seen: these are weeds that grow very luxuriantly, drawing much from the ground or soil, when among the crops, as is frequently the case in many places. They should always be drawn out as much as can be done in such cases in hot weather: they are mostly weeds of the annual or biennial kinds. It is said by Withering, in speaking of the uses of them, that should a heap of clay be thrown up, nothing would grow upon it for several years, did not the seeds of the spear thistle, wafted by the wind, fix and vegetate thereon; that under the shelter of these, other vegetables appear, and the whole soon becomes fertile.

They are never to be trusted among crops, but be kept well cut or pulled up in their early growth. See *CARDUUS Lanceolatus*, *Pratensis*, and *Acaulis*. Also *THISTLE*.

Colt's-foot is a weed that is very apt to abound in hard tilled land. It has been said that the only time to destroy this weed, is by cutting it up in those months when it begins to throw out its flower, at which time, if so cut, it

WEED.

will bleed to death; these months are February and March, at which time all land in fallow, which is subject to this weed, should undoubtedly be ploughed and harrowed down, which would, without doubt, check the growth of, and very much weaken the weed; but when neglected at this period, it will soon afterwards ripen its seeds, which furnished by nature with feathers, fly all over the country, and establish themselves very quickly on cultivated land, and banks of earth newly thrown up. This weed may, it is said, be considerably weakened by repeated summer ploughing, and be afterwards, for the most part, weeded out by hand, as the ground is thus rendered light. It is a weed which in Gloucestershire is not found, except on soils that are poor in their nature, and subject to moisture. The obvious remedies are consequently fertilization by manure and the removal of wetness by draining. See *TUSSILAGO Farfara*.

Groundsel is a mischievous and troublesome disgusting weed, not unfrequently found in fallows, on good free soils rendered fine by cultivation, as its seeds ripen quickly in such cases, and fly over the country with the wind: it is a weed that should be got quit of in time by being pulled out, or turned under by the plough, and the seed of it be by no means permitted to ripen and disperse. See *SENECIO Vulgaris*.

Corn marigold, goulans, goul, or buddle in Norfolk, is an extremely troublesome weed in some soils: it is an annual, producing seeds plentifully, which vegetate whenever the land is cultivated, and very commonly in the crops of corn: it would, without doubt, it is supposed, be destroyed, as other annual feeding weeds, by early and complete fallowing to bring the seeds into vegetation in due time, and afterwards ploughing them under. According to Withering, in Denmark, there is a law to oblige the farmers to root it up: and it is said to be stated in the second volume of the "Statistical Account of Scotland," that the late sir William Grierson, of Lag, held *goul* courts as long as he lived, for the purpose of fining such farmers on whose growing crop three heads or upwards of this weed were found; and it has been observed, that some regulation of police for fining those who harbour weeds, the seeds of which may be blown into their neighbour's grounds, has no injustice in the principle of it.

It is stated in the Berkshire Corrected Report on its Agriculture, that it may be destroyed by the application of chalk as a manure, as well as by extirpation.

On the authority of the *Flora Rustica* it is noticed, that if this weed be cut when young in flower, and dried, horses will eat it. See *CHRYSANTHEMUM Segetum*.

Corn mint is a weed that is said by the writer of the Corrected Report of the Agriculture of the County of Gloucester, to be common on damp soils; and that it increases fast by the root, where, for want of frequent ploughing, dragging, and other tillage, it is neglected. See *MENTHA Arvensis*.

Corn camomile is a weed that is sometimes prevalent in corn-fields: it is very prolific in seeds, which should never be suffered to shed, as in that case it would be multiplied to an almost endless degree. See *ANTHEMIS Arvensis*.

Stinking May-weed is a plant of this kind that is common in corn-fields among the crops, but which is often confounded with the above and other weeds of that sort, from which it is to be distinguished by its disagreeable smell: it is very injurious to corn-crops, and should be prevented or destroyed by good fallowing, or by being timely rooted out of the land. The Gloucester Report on its Agriculture states, that maithe or mathern there often overruns a whole field, particularly when planted with peas, so that only the

white blossom of the weed is to be seen. The only chance of destroying this stinking weed is, it is supposed, by the drill husbandry, where room is left for the free use of the hoe. In the broadcast mode the weeds must be pulled out by the hand, which is not only tedious, but, in some measure, dangerous, as there is a noxious quality in the plant which is liable to injure the hands of the weeders, if they happen to have fores on them. See *ANTHEMIS Cotula* and *MATRICARIA Chamomilla*.

Blue bottle is a weed that is common in corn where the tillage of the land has been imperfect, or too long carried on, and continued without cleaning by means of turnips or fallow: it is an annual weed with a somewhat elegant blue flower. It is very common in the corn-fields of Shropshire and Lancashire, as well as in some other counties. It is said that, in Gloucestershire, blue bonnet, knapweed, or corn flower, is a weed common in some fields, principally where the soil is loamy and mixed with pebbles. It is advised to be extirpated at first by the hoe, and, when grown to blossom, by the hand. See *CENTAUREA Cyanus*.

Great knapweed is a perennial corn weed, growing in tufts of many stems or stalks from the same root; and which is to be destroyed in the fallow, or by being weeded out of the crop. See *CENTAUREA Scabiosa*.

Pansy is an annual flower weed that is often found among corn-crops in different districts, where it is produced by seeds that have not been destroyed in the preparation for the corn-crop. It is seldom very hurtful, but when abundant should be weeded out in some way or other. The beauty of the colours of its flowers has gained it a place as an ornamental plant. See *VIOLA Tricolor*.

Corn horse-tail is a weed often met with in corn-land, the fertile stem of which appearing early in the spring, with that of colt's-foot, and decaying before the other part of the plant appears. The author of the paper already noticed states, that Loefel says, if ewes in lamb eat it, abortion is the consequence; but it is believed that sheep or cows will not eat it, unless compelled by hunger. It is to be destroyed by the same kind of tillage and extirpation, as that recommended for colt's-foot. In the Gloucester Report on Agriculture, it is stated to be found only on moist soils, and cannot be easily overcome, but by draining and completely removing the wetness. See *EQUISETUM Arvenfis*.

Fern is a weed not uncommon in corn-fields on dry sandy land: it is a hardy perennial plant, tenacious of growth, and striking a long tap root into the ground, beneath the reach of the plough, which shoots up vigorously when the sun becomes powerful: it prevails largely and strongly on some deep dry hazel loamy soils. In order to destroy it, after soaking rain, it should be drawn or deeply ploughed up; though, in some cases, it will require much pains and attention to get quit of it, especially on land where it has been established for a great length of time. See *PTERIS Aquilina*.

There are different other weeds which are occasionally met with in lands of this sort, but which, as their nature, habits, and effects, have not been well or fully ascertained, they have not been noticed here.

Weeds injurious in Meadow and Pasture Lands.—From its not having yet been fully and exactly decided which are to be considered as noxious and hurtful, and which beneficial and useful plants, in the herbage of grass-lands, it may be proper and of utility to consider them under the heads of such as are really found prejudicial in such situations, and such as have not been discovered to be actually so, and the particular qualities of which are not well known.

Of the first sort are those which are described below, on the authority of the writer of the paper on weeds mentioned above, and that of some others.

Cotton grass, hare's-tail, or moss crops, are weeds that grow in bogs or boggy meadows; and with the down of which poor people stuff their pillows, and make the wicks of candles. This weed is a certain indication that drainage has been neglected, and that it is of course necessary to be attended to and practised, in order to restore the meadow or other such land to the proper state for the growth of good herbage. See *ERIOPHORUM Vaginatum*, and *Polyflachion*.

Hog weed, or cow parsnip, is a weed often found in meadows, but which is too coarse and of too weedy a nature and appearance to be suffered to abound in well cultivated and managed grass-land, though, it is believed, that cattle will eat it either green or in the state of hay: it is thought that it may probably be weakened or destroyed, by annually cutting up in its early growth. See *HERACLEUM Angustifolium*, and *Sphondylium*.

The latter is frequently met with, especially in moist meadows in Cheshire.

Wild cicely, or cow-weed, is a common weed in orchards, hedges, meadows, and pastures. Cattle are said to be fond of it in the spring, but it is too coarse to be permitted or encouraged among good herbage of the grass kind; and as it flowers, and ripens its seeds before the grasses, it is a bad and improper addition to the grass-plants of both meadow and pasture lands: it is frequent in the meadows of Cheshire. It has been suggested, that this and the last noticed plant may probably be worthy of a trial in cultivation by themselves, as being of luxuriant growth, they would yield a large produce: their value has not, however, yet been fully ascertained; nor especially in this method of culture and management. See *CHEROPHYLLUM Sylvestris*.

Garlick, in the wild state, is a weed that is frequently found in meadows and pasture lands, and which is considered as greatly injuring the latter when used for cows. It is said to give a disagreeable flavour to the produce of the dairy, as butter and cheese, but it does not seem that cows much dislike or refuse to eat it. It is supposed, however, that this may probably happen on account of its being so much blended and intermixed with the other grasses, that they cannot avoid cropping it a little. This weed is frequent in the cow pastures of some parts of Lancashire, Gloucestershire, and most probably many others. See *ALLIUM Ampeloprasum*.

Ramson is a weed that is found in some meadows and other grass-lands, but more commonly in the hedges; other plants will not, it is said, flourish near it: cows eat it, but it, like the above weed, gives their milk and its produce a garlic flavour: it should, of course, be weeded out of grass-lands as soon as discovered and be destroyed. See *ALLIUM Urfinum*.

Rushes of different sorts are a sort of weed-plants which are not unfrequently met with in meadows and pastures, especially when of the cold clayey kind, and which are a sure indication that the land, in such cases, wants the superfluous wetness removed; which, when it has been effected, always gives way to better herbage, though their extirpation and destruction afterwards will be promoted and accelerated by top dressings of ashes and other matters. In the Gloucester Report on its Agriculture, it is stated, that the common rush is an inhabitant of soils that are moist and strong, that it abounds in the furrows of pasture-lands, and on the *meers* or strips of grass-land left between the grounds in the vale of that county, as the dividing mark of different

properties, and that it is destroyed in the manner above. See *JUNCUS*, different sorts. Also *RUSH*.

Docks are weeds that are found in strong four heavy land of the meadow and pasture kind. As these weeds are refused by most sorts of domestic animals, they should be rooted up after rain, and every pains be taken to destroy and remove them from grass-land, which they injure greatly by their shade, and by causing the herbage about them to become rank. They are said to be eaten only by fallow-deer, by which their flourishing in parks and pleasure-grounds is prevented. It is remarked that in Gloucestershire docks are extremely injurious to the herbage of pasture-lands, but that if taken in time they may be easily conquered. If, however, they are permitted to ripen, they leave an immense quantity of seed for future crops; and, that being perennial, the evil is increasing in such a multiplied proportion, as almost to exclude the growth of all other plants. In a large meadow adjoining the county-town, these weeds have matured and shed their seeds, it is said, so often, and for so many years, that, at the time of mowing, the whole appears like a crop of docks. Where these weeds are not got up by the roots, it is useful, in some cases, to cut through the stalks under the ground; and to repeat the practice as shoots are again thrown up. See *RUMEX Crispus*, *Acutus*, *Obtusifolius*, &c. Also *WEEDING Dock-Spit*, &c.

Bisfort is a weed that, in some places, occupies large portions or patches in meadows, to the injury and destruction of better herbage: it is a perennial, but may without doubt be weakened or destroyed by rooting up repeatedly. The root is one of the strongest vegetable astringents, and may probably be applied to many purposes in the arts with benefit. It is the inhabitant of moist meadows in Cheshire. See *POLYGONUM Bisfortia*.

Wild campions are weeds often found abundantly in pastures formed from ploughed lands: there are two sorts, as those with white and red flowers. Care should be taken to exterminate them from such pastures by proper following the land when in the broken up state. See *LYCHNIS Dioica*, &c.

Goose-tansy, silver-weed, or feathered cinquefoil, is a weed common in many pastures laid down from the arable state, but generally untouched by cattle: it should therefore be destroyed and got rid of in the tillage state of the land, and by keeping it free of stagnant wetness. See *POTENTILLA Anserina*.

Tansy is a weed that is found in Gloucestershire, in some pastures by the side of the Severn, and in a few other places in that county, but not in abundance, as well perhaps as in some others, especially in the northern parts of the kingdom. It is an unpleasant weed, it is said, which should be eradicated by the spade, or some other proper means. See *TANACETUM Vulgare*.

Pilewort is a weed that flowers very early in the spring, and abounds in shady or moist pasture ground; it sometimes occupies much room in some meadows, and clinches other plants which grow near it; and not being eaten by cattle, it should certainly be extirpated: nothing discourages its increase more than coal and wood-ashes, the writers of the *Flora Rustica* suppose. See *FICARIA Verna*, and *RANUNCULUS Ficaria*.

Lousewort, or red-rattle, is a weed found in moist meadows and pastures, and, it is thought, rarely but where the land is in want of being rendered dry: it is said to be very disagreeable to cattle, and injurious to sheep, giving them the scab, and occasioning them to be overrun with vermin: it is believed, however, that these injuries are principally caused

WEED.

caused by the unwholesome nature or state of the land on which it grows: it may be destroyed, it is supposed, by removing the wetness and top dressing. See *PEDICULARIS Sylvatica*.

Yellow-rattle is a weed that is said to grow generally in moist meadows in the county of Gloucester, and which ripens its seeds, and sheds them before the time of mowing, when the dry husks make a rattling noise under the scythe: at this time, it contains no nutritious juice at all, though, when green, oxen and horses will sometimes eat it rather eagerly, and at other times refuse it. Having, however, no desirable quality to recommend its cultivation, and oftentimes overrunning large patches of ground, it should be eradicated and destroyed; and being a biennial, this, it is thought, may easily be done, by grazing the land for three or four years in succession, and taking care that the stalks that are left by the cattle be skimmed off by the scythe before they are ripe enough to shed their seeds, or while they are in full blossom. In regard to its removal, it is stated, that a farmer near the northern borders of the same county, shewed the writer a sloping piece of grass-land which had been overrun with rattle: without any view to the destruction of that he conducted the water of an adjoining stream, as well as he could, over the piece which was not, however, wholly watered; but it proved that on the watered part, the rattle was destroyed, while it continued to grow on the portion which had escaped. No plant is more frequently found mixed with the grasses in the meadows of Cheshire than this; but as it has nothing to recommend it, and the farmers dislike it, the removal of it should be effected to make way for better herbage. See *RHINANTHUS Crista-galli*.

Dyer's-broom is a weed that is seen very abundant in some pastures on strong and moist land, whence, as it is often troublesome, it should be grubbed up, and be got quit of. Wood waxen, dyer's-weed, or base broom, grows abundantly, it is said, in many parts of the vale of Gloucestershire, but generally on dry pastures: it is refused by no cattle but sheep; yet, being inferior to good grasses, should be rooted out, except in places where, as in the neighbourhood of Bristol, it is collected and carried while in full blossom to the manufacturers, who, by boiling and other means, extract a fine yellow colour from it. See *GENISTA Tinctoria*.

Rest-barrow, or commock, is said to be a weed often found in pastures, where it is eaten by cattle, especially the younger shoots of it; but that it is too coarse and rubbishy to be suffered to increase, and should consequently be rooted out or grubbed up as soon as possible. In Gloucestershire it is said, too, to be a most troublesome weed, and a pretty sure proof of want of attention, culture, and manure; as by the two former it may be easily cleared from arable land, as has been seen, and by well-rotted horse-dung even pasture-lands may be assisted; but that rather than such a disgusting plant should continue to grow, where its place might be supplied with good herbage, neither labour nor expence should be spared. The little advantage it gives to sheep, which will eat the young shoots before the prickles are formed, is not, it is supposed, a sufficient inducement in the calculation of a good farmer to leave it undisturbed. In the parish of Elmore, in that county, there is, it is said, a pasture-ground almost covered with it, which lies too far from the farmhouse to have manure easily conveyed to it. In this case, the occupier tried the experiment of drawing it out by the roots, but discontinued it from the idea that it came up with greater strength, and in more abundance the succeeding year. The fact is, that the business is but half done, if the roots are not entirely removed, as every broken piece will

throw out shoots; and from long continuance of the plant on the spot, and the annual shedding of the seeds of it, it is probable that a new crop will arise in the following spring: but the farmer should not be discouraged, it is said, on his first attempt; since, by continually watching the weeds in their early growth, and cutting them off with the hoe, they would gradually be destroyed; and the process would be much assisted by well dressing the places with rotten horse-dung, as suggested above. See *ONONIS Spinosa*, and *Arvensis*.

Common thistle is a most noxious weed among grass herbage: it has strong roots which shoot out in a lateral manner, and is a perennial plant of vigorous growth in some soils. It may be got quit of by cutting it off within the ground, or by being rooted up; for the former sort of work the best time is when the plants are coming into full blossom, as they then become soonest rotten and destroyed in their hollow root parts; and for the latter in pasture-lands when the ground is well soaked with rain, and they can be drawn easily. They are sometimes very hurtful to the hay lands in the vicinity of the metropolis, where the management is bad. See *SERRATULA Arvensis*, and *THISTLE*.

Rough large thistles, or boar-thistles, are weeds of a very troublesome nature among grass-crops, and which are always to be got rid of without delay. They are generally mown or otherwise cut over, but are much better rooted or drawn up. It is remarked by the writer of the *Corrected Account of the Agriculture of the County of Gloucester*, that thistles of all kinds are very unpleasant weeds in grass-lands; either when green or dried with the hay, they annoy the cattle in feeding, and consequently should never be permitted to grow long on any such land; to prevent their growing at all, is, it is thought, perhaps impossible, but the increase of them may be checked by early attention: while, however, they are left to be mown with the grass, or to remain undisturbed in the highways during the summer, the seeds will be dispersed by the wind in various directions over the country: until a method be therefore adopted to correct the evil in its infancy, the labour bestowed by good farmers for the extirpation of this weed will not, it is said, produce a complete effect, although it will prevent the plant from being carried to the mow in a state of equal maturity with the hay, and its seeds afterwards from being dispersed with the dung in the fields. Was every farmer to do the same, the encouragement to persevere in the practice would be powerful; but that it is not probable, that a farmer will expend much in doing what the negligence of a neighbour will render ineffectual. Some of these thistle-weeds are annual, others biennial and perennial; consequently, where the distinction is not known, the safe method is, it is said, to cut the root with a paddle, deep in the ground, or to draw up the root; and that this should be done for the first time in the spring, and again on the lattermath in autumn. See *CARDUUS Lanceolatus*, &c. Also *THISTLE*.

Cudweed, or chafeweed, is a weed said not to be uncommon in pastures from arable land. It has been seen abundantly in an upland pasture after barley, where the clover had failed of success; cattle refuse it, but it has been supposed to be successful in the bloody flux of cattle and of the human species: it seldom appears much in a grass-crop, or especially when the artificial grasses succeed well. See *GNAPHALIUM Germanicum*.

Ox-eye, white marigold, or great daisy, is a weed common in some pastures, and not grateful, but which seldom abounds so as to be much injurious to the grass, and which is easily drawn out by the hand or other such means. See *CHRYSANTHEMUM Leucanthemum*.

Black knap-weed is a common and abundant weed in some moist and cold meadows and pastures, where it is a very bad plant, being coarse, hard, and stubborn, seldom touched by cattle, either in the green or dry state, and not extirpated from the ground without much difficulty: it is a perennial weed, which increases much by the root, according to the *Flora Rustica*. It is supposed that it might probably be much weakened and reduced, and be extirpated by degrees by drawing up after rain. It is stated too, that in Gloucestershire the common black knap or knob-weed, provincially hard heads, is a vile and worthless weed, which cattle of no kind will touch, in any state; and yet it is suffered, on some pastures, to grow and increase to such a degree, as to exclude the appearance of almost every other plant, and, though useless, is mowed with the other herbage, and preserved for winter fodder. That it is a weed which indicates poor land, though probably, by the use of soaper's ashes, it might be conquered, otherwise the ground should be ploughed up and converted to a better purpose. The writer of this article lately saw it wholly covering a poor pasture field in the north of Lancashire, to the exclusion of all useful grasses. See *CENTAUREA Nigra*.

Sedge-grasses, various sorts, are weeds that are most common in cold, old, sour, moist clayey lands of the meadow and pasture kind, undrained and unimproved; in which they are said, in some places, to occupy the whole surface: they are extremely hardy, and flourish where scarcely any thing else will grow: seem produced by nature from this principle in her economy, that a bad plant is better than none, for these plants are not eaten by any sort of cattle which can get any thing better; yet, upon getting quit of the superfluous moisture or wetness, and top-dressing the land, it will commonly give way to a finer and more valuable herbage. See *CAREX*.

They have provincially the titles of hard-grafs, iron-grafs, and carnation-grafs, sometimes applied to them.

Common nettle is a weed sometimes growing in tufts on pasture-land, where it should always be rooted up, as it will prevent the growth of good herbage, and render the grass rank near it: asses are said to be fond of it, and cows eat it in the state of hay. See *URTICA Dioica*.

Mosses, various sorts, are weeds that are sometimes said to spread on pasture and other grass lands, and, it is believed, indicate that the herbage is starving and torpid, and stands in need of a stimulus to quicken its growth: proper top-dressing should be used, and the wetness be removed, if necessary. Treading by sheep, and scratching the surface by means of fine-teethed implements, have likewise been found of great utility. See *MUSCI*, and *Moss*.

Such plants as the above must be considered as proper and necessary to be extirpated from grass-lands of most kinds; but there are various others which are of less importance, and the characters of which are more doubtful, and their uses not so well determined and decided upon.

Of this latter sort or class, the following may be noticed as being mostly improper in such situations.

Crowsfoots, butter-flower, butter-cup, king-cup, or gold-cup, are plants almost every where found in meadow and pasture lands. The pile-wort is common in some places, and the bulbous-rooted sort, it is observed, has knotty roots, rises little above the ground, blossoms early in the spring, and is chiefly found in meadows that are rather moist, being eaten only by sheep. The other sorts are common in the meadows and pastures everywhere, being very abundant in the hay-grounds near the metropolis. Their good qualities in such lands have been much questioned and disputed by many; but the writer of the paper already noticed is inclined

to think favourably of them, especially as promoting the digestion of the live-stock that feed in such pastures; and as not having been discovered to be injurious in such situations by farmers in their long experience. The writer of the Gloucester report, however, states, that the several sorts of crowfoot, provincially termed crazys, which in the spring throw a yellow veil over the meadows, are to be reckoned among the useless weeds, having little to recommend them to notice but their gaudy appearance. That the three latter sorts are acrid and biting to the taste, and are therefore rejected by cattle nearly alike. It is indeed said, that the creeping crazy is more mild and palatable to some cattle, though it is to be suspected that cattle eat it rather from necessity than liking; as from its spreading along the surface, it becomes so matted with the herbage, that it must be taken up, in some degree, with it. The stalks of the two others are left standing when the ground is quite bare about them; yet, when made with the hay, they are said to lose the pungent quality; and the brightness of the blossom in the rick, is always a sign of the whole having been well harvested.

All the sorts of this tribe of plants, though pleasant to the eye in meadows and pastures, in consequence of their display of yellow flowers, are, it is said in the Berkshire report, injurious to the herbage, and little relished by animals of any kind. Although difficult to be eradicated, some of the larger sorts of them may be reduced greatly by proper care and attention. See *RANUNCULUS Ficaria*, *Bulbosus*, *Repens*, and *Acris*.

Wild mint is a plant found in moist pastures, and which prevents the coagulation of milk; so that when cows have eaten it, as they are apt to do largely at the end of summer when the pastures get bare, their milk can hardly be made to yield cheese; a circumstance which occasionally puzzles the dairy-maids. It is a plant that should be removed from pastures, and which, it is supposed, may be weakened by effectually removing the wetness of the land. See *MENTHA Arvensis*.

Marsh marigold is a plant that occupies much space, and which is dangerous to cows. It should consequently be removed from pastures and other grass-lands. See *CALTHA Palustris*.

Water hemlock is a plant supposed poisonous to horses, and should therefore be eradicated from pasture-lands. See *THELLANDRIUM Aquaticum*.

Water cowbane, meadow-saffron, and treacle-mustard, are plants in pasture and grass lands, that are said to communicate an unpleasant odour to the milk of cows, and to be sometimes fatal to them. When abundant they ought to be removed from such lands. See *CICUTA Vireosa*, *COLCHICUM Autumnale*, and *THEAPSI Arvensis*.

Mouset-ear scorpion-grass is a plant that often proves fatal to sheep, it is said, and should of course be extirpated from sheep-walks. See *MYOSOTIS Scorpoides*.

Rag-wort is a plant in grass-land which cows and horses refuse, and which sheep will only eat when very young: it is a plant that is stated, in the Cheshire Report on Agriculture, to be regarded as worse than useless both in meadows and pastures. That it frequents rich soils only; and that the farmer there often exhibits the keddle-dock, as it is provincially termed, as a proof of the goodness of his land. That while his vanity is flattered by its presence, he not only neglects to extirpate it, but frequently suffers it to spread over one of his best pieces of land, to the injury of himself and the annoyance of his neighbour. It is said that by mowing it is prevented from propagating its seeds; but that the roots are not destroyed. That this is best effected either

WEED.

either by eating it down while young with sheep, or pulling it up by the hand. This last should be done when the ground is moist, in order that no considerable fibres may be lost or left in the land, as if there are the roots will strike again. See *SENECIO Jacobæa*.

Meadow sorrel is a plant common in meadows, and especially where the soil is strong and rather wet: it is a coarse plant that is injurious by its shade, and seeds in good grass-lands. See *RUMEX Acetosa*.

Wood or meadow anemone is a plant common in meadows, though disregarded by farmers; the whole plant is said to be acrid. Withering asserts, that when sheep that are unaccustomed to it eat it, it brings on a bloody-flux. See *ANEMONE Nemorosa*.

Eye-bright is a plant common in pastures, and refused by cattle in general; consequently occupying the place of a better plant. See *EUPHRASIA Officinalis* and *Odontitis*.

Dandelion is a disagreeable plant, though common in grass-lands in most districts: it is said to be considerably diuretic, and on that account may probably have a good effect on cattle at first going to grass: it is coarse, but good in hay with grasses. See *LEONTODON Taraxacum*.

Yarrow, and *sneeze-wort*, are plants common in pastures, but indifferent to cattle-stock. The former has been recommended for poor land. The common yarrow has been found plentifully intermixed with the herbage in the vale part of the county of Gloucester, where much fed with horses. Some have, it is said, supposed, that cattle are not averse to it; but it has been observed, that this weed has remained uneaten until every blade of grass has been cropped close to the ground, and therefore that it should be extirpated by the spade or some other means, such as the three-pronged fork, at the expence of manual labour. See *ACHILLEA Millefolium* and *Piarnica*.

Orchises of several sorts are plants that are common in most meadows, having broad, entire, spotted leaves in general, and large bunches of pale or purple flowers. They generally remain untouched by most, or all sorts of cattle-stock. See *ORCHIS Maculata*, *Bifolia*, &c.

Plants of this sort have hitherto been much too little examined and inquired into, in so far as relates to their utility and importance, or the contrary, for the uses of the farmer, to afford any thing satisfactory on the subject; but that a great many such plants should be rooted out of grass-lands of different kinds there can be no sort of doubt. This would render the meadows and pastures much better for the purposes of hay, and the pasturing and feeding of live-stock of every sort, and be greatly beneficial to the farmer in many ways.

Weeds injurious in waste and uninclosed Lands.—It is stated by the writer of the paper on weeds, that those considered as particularly hurtful to such land, are not very numerous; for though many sorts of plants, useless as the food of domestic animals, grow there, yet, as there is no possibility of introducing any thing better until such lands are appropriated and improved by cultivation, they can hardly be conceived as noxious, so long as nothing better can be put in their stead. That, as such lands in their present condition are useful only as sheep-walks, or for producing fuel, the bettering of them, in the former respect, is an object deserving of attention, particularly as such amelioration would render them of greater value in case of inclosure, and would much shorten the business of bringing them into the state of improvement. See *WASTE Land*.

The weeds that encumber such lands, and reduce their value as sheep-walks, are considered as of two kinds; the common upland rubbish, and the bog produce of plants:

the former smother the land, so as to prevent the growth of better herbage; and the latter are generally hurtful to animals that feed on them, either from their own nature, or because the land on which they grow is uncomfortable for and unwholesome to the health of them, especially to sheep.

Upland weeds are all those that rise in high barren situations, and which chiefly consist of heaths of different sorts; furze or gorse, the petty whin, or hen-gorse, and broom, but which is more commonly met with in neglected dry lands of the arable kind: these should all, it is said, where the ground is of tolerable staple, or depth of mould, be burnt off, or grubbed up, early in the spring; and if the land be afterwards sown with grass-seeds of the hay kind in moist weather, it will much improve the herbage: the fern should also be mown, and carried off in the summer, the value of it as litter being well worth the labour and trouble. See *ERICA*, *ULEX Europæus*, *GENISTA Anglica*, *SPARTIUM Scoparium*, and *PTERIS Aquilina*.

Bog weeds are those that arise in swampy places, and are caused by stagnant moisture or wetness, being principally cotton grasses, matt-grass, rushes of several sorts, red-rattle or louse-wort, marsh, St. Peter's-wort, kingspear, which last two are of but little consequence in themselves: they, however, indicate boggy land; and in their company are often found purple-flowered money-wort, sedge grasses of several sorts, &c.: all which would give way to better herbage, upon the stagnant wetness of such bogs being removed, which should, it is said, be done by a rate, levied on the inhabitants of the neighbourhood, having right of common upon such wastes. See *ERIOPHORUM Polystachion* and *Vaginatum*, *NARDUS Striata*, *JUNCUS*, *PEDICULARIS Sylvatica*, *HYPERICUM Clodes*, *NARTHECIUM Ojifragum*, *ANAGALLIS Tenella*, and *CAREX*.

The disease, termed the rot, in sheep, which so commonly arises in these situations, has been often attributed by stock-farmers and others to the fun-dew, marsh penny-wort, and common butter-wort, weeds found in such lands; but it is more probably caused by the flat insect known by the name of fluke, *fasciola hepatica*, which is not unfrequently met with in such watery grounds, sticking to different parts of the plants, and which has been discovered in the diseased livers and bile ducts of sheep thus affected. See *DROSEREA Anglica*, *HYDROCOTYLE Inundata*, &c.

The writer just noticed suggests, that if the country should not yet be ripe or ready for inclosing all the commons and waste lands, the improvement of their staple by measures of this kind, by destroying weeds and introducing better herbage, by removing the wetness of the bogs, and destroying the aquatic weeds growing thereon, would better their present state, and improve their value to the public, would render them capable of maintaining a greater number of better sheep, and preserve the stock in better health, as well as render the land more susceptible of a rapid and easy improvement by cultivation, whenever the time may arrive for their inclosure, and for such full amendment of their condition.

Weeds injurious in Hedges and other such Fences.—It is remarked in the paper on weeds and weeding, that all kinds of them are hurtful to young hedges, which constantly require to be well cleaned and freed from them for three or more years after planting, as otherwise the young quick or other plants would be choked and destroyed; and that there are also some kinds of weed-plants which very much injure old full-grown hedge-fences. That many kinds of weeds growing in hedges are a great nuisance if the seeds be suffered to ripen, because such seeds are liable to be carried into cultivated

WEED.

cultivated land by the wind; that there are some kinds of hedge-weeds, too, which bear the character of being injurious to live-stock; these, if the observation be well founded, ought, it is said, to be well cleared from the hedges that such stock frequent; and that, lastly, the improper species of the vegetable kingdom, composing or growing in hedges, may be termed hedge-weeds, because they prevent the main object and end of such hedges, that of dividing, fencing out, and defending the land in a proper manner.

The most hurtful weeds and plants of this sort are,

Catch-weed, or cleavers, a weed that has a tendency to choke and injure young hedges, by means of its numerous creeping and twining rough branches: it should, of course, be well cleaned out in due time, before it spreads itself much in the bottom of the fence. See *GALIUM Aparine*.

Great bind-weed is a plant of this sort that is injurious in some hedges, by twining round the growing quick or other plants, and restricting their growth: its roots should consequently be extirpated from such situations, which may probably be worth collecting for medicinal uses, as the inspissated juice of them compose scammony, a powerful purgative remedy. It is eaten greedily, too, by hogs without injury. See *CONVOLVULUS Sepium*.

Great wild climber is a weed-plant common in hedges, and which, in the chalk counties, is said provincially to be called old man's beard, from the hoary appearance of the plant after flowering, the seeds being furnished with numerous grey hoary tails. It is very injurious to hedge-fences, as the leaf-stalks twine about any thing they can lay hold of, and thus support the plant, which is large, luxuriant, and heavy, without any strength to support itself, and by its weight hauling down, obstructing the proper growth, and deforming the fences of this kind. Withering remarks, that the fine hairs that give the cottony appearance are, he apprehends, too short to be employed in manufacture, though, it is probable, they may be used to advantage for the stuffing of chairs. See *CLEMATIS Vitalba*.

Wild hop, ladies' seal, or black bryony, and wild vine or bryony, are all weed-plants common in hedges, where they are supposed to be somewhat injurious to the hedge-fences. They do mischief in these situations, by crowding and smothering up the hedge-plants, and preventing their healthy and vigorous growth, as well as by taking away the proper nourishment from their roots. See *HUMULUS Cupulus*, *TAMUS Communis*, and *BRYONIA Divica*.

There are other spreading, twining, and climbing weed-plants, which are occasionally very injurious and troublesome in hedges; such as the common ivy, which spreads and creeps on the banks, and runs up and winds round the stems of the plants, greatly injuring and impeding their growth and strength; the honey-suckle, which binds itself closely about the stalks and branches of the hedge-woods, doing them much injury in different ways; and the briar, which extends its rampant shoots in various directions, to the great annoyance and mischief of the hedge-plants in many cases. All these should be eradicated and cleared out from hedges in most cases, as they constantly tend to weaken and render them in bad condition. See *HEDERA Helix*, *LONICERA Periclym nun*, and *ROSA Canina*.

Sow-thistles, large rough thistles, knap-weeds, and ragwort, are weeds that have been already noticed, and are great nuisances in hedges, if their seeds be suffered to ripen in such situations. The common nettle, too, is sometimes found in hedges to their great injury. They should all, therefore, be extirpated and cleared out from hedges in their early growth, to prevent future increase.

In addition to these, the writer of the above paper has

given the following, the seeds of which are furnished with feathers too, and they are capable of being carried to a great distance.

Yellow devil's bit, wild lettuce, yellow hawk-weed, bushy hawk-weed, and smooth hawk's-beard, are weeds often troublesome in hedges, and which should be kept well weeded out at an early period. See *LEONTODON Autumnale*, *LACTUCA Virosa*, *HIERACIUM Murorum et Umbellatum*, and *CREPIS Tefforum*.

Burdock is a well-known plant of the weed kind, that should not be suffered to perfect its seed in hedges, as it is of very luxuriant growth, and of course very injurious and disagreeable in such situations. Withering asserts, that before the flowers appear, the stems, stripped of their rind, may be boiled and eat as asparagus; and that when raw, they are good with oil and vinegar. See *ARCTIUM Lappa*.

Dog's mercury is a weed said to be noxious to sheep, and which is very common and abundant in some hedges, appearing very early in the spring, when sheep-food is the most scarce; on which account it is thought still more dangerous, if it be so at all. When in very large quantity it may be hurtful to hedges, and should be kept under. See *MERCURIALIS Perennis*.

Barberry is a frequent plant in some hedges; if found to really possess a blighting quality, it should be removed from the hedges of corn-fields. See *BERBERRIS Vulgaris*.

It is advised by the author of the above paper, that these, as well as other plants of a similar nature, together with all luxuriant weeds and shoots of the bramble kind, and whatever else grows beyond the bounds of the hedge-fence, should be brushed out of such hedges about the middle of the summer, as is very often done in some counties, as Staffordshire, for the sake of their ashes, which are worth all the labour and expence incurred in burning them, &c.

Weeds injurious in Woods and Plantations of different Kinds.—The weed-plants which are necessary to be considered under this head, are not very numerous: those which are given below are the chief of such as are peculiar to or commonly found in situations of this nature, where no art has been used. They are the most common herbs and plants which are spontaneously produced in woods and plantations without attending to the timber and underwood sorts; but many other kinds are to be met with, which are less common, and which have been less noticed and considered.

Enchanters' nightshade is a weed found in the woods of Bedfordshire, and some other counties, and by no means uncommon. See *CIRCÆ Lutetiana*.

Wood-reed is a weed met with in many woods. See *ARUNDO Arenaria*.

Woodroffe is a weed common in many woods about Enfield, in Staffordshire, and Berkshire. Sometimes very plentiful. See *ASPERULA Odorata*.

Wild angelica is a weed common both in woods and hedges, in many places. See *ANGELICA Sylvestris*.

Solomon's seal, or wood lily, is a weed found in woods in many different parts of the kingdom. See *CONVALLARIA*.

English hyacinth, or hare-bell, and willow herbs, are weeds in some woods. See *HYACINTHUS non Scriptus*, and *EPILOBIUM*.

Bilberry is a weed met with in moist woods in many parts of the country. See *VACCINIUM Myrtillus*.

Wintergreen is a weed-plant met with in the moor-land woods

WEED.

woods in Staffordshire, and some other counties. See PYROLA.

Wood-forrel is a weed very common in woods. See OXALIS *Acetofella*.

Wood-spurge is a weed frequently met in woods, situated in a clayey soil. Plentifully in Needwood-forest, in Staffordshire. See EUPHORBIA *Amygdaloides*.

Raspberry, dewberry, and common bramble, are weeds common in most woods, in some of the forts. See RUBUS.

Wild Strawberry is a weed common in some woods. See FRAGARIA *Vesca*.

Tormentill is very common as a weed in some woods. See TORMENTILLA *Reptans*.

Herb bennet, and wood anemone, are common weeds in such situations. See GEUM *Urbanum*, and ANEMONE *Nemorosa*.

Wood crowfoot is a common weed in woods on a clayey soil. See RANUNCULUS *Auricomus*.

Stinking Hellebore is a weed in woods, in many parts of the kingdom. See HELLEBORUS *Eatidus*.

Wood sage, betony, hedge-nettle, and bastard baum, are weeds of the common wood kind. See TEUCRIUM *Scorodonia*, BETONICA *Officinalis*, STACHYS *Sylvatica*, and MELISSA *Melissophyllum*.

Cow-grass, or cow-wheat, is very common in many woods, and said to be an excellent cow-herbage; but little found in pastures, in any situation. See MELAMPYRUM *Pratense*.

Fig-wort, and coral-wort, are weeds in some woods. See CROPHULARIA *Nodosa*, and DENTARIA *Bulbifera*.

Pea-everlasting is a luxuriant weed-plant, that has been seen with the stem five or six feet long, in a wood in Rutlandshire. See LATHYRUS *Sylvestris*.

Wood-vetch, wood-peasling, St. John's wort, shrubby hawk-weed, fow-wort, hoary groundsel, golden-rod, butterfly-orchis, friary-blade, sedge-grasses, and spurge-olive, or spurge-laurel, are all plants of the weed kind in woods in different places. See VICIA *Sylvatica*, OROBUS *Sylvatica*, HYPERICUM *Perforatum*, HIERACIUM *Sabadum*, SERRATULA *Tinctoria*, SENECIO *Crucifolius*, SOLIDAGO *Virgaurea*, ORCHIS *Bifolia*, OPHRYIS *Ovata*, CAREX and DAPHNE *Mezereum* and *Laureola*.

It has been remarked, that as no sort of cattle can be properly introduced into these situations, in the early growth of the woods, there appears no particular room for the choice of the under herbage; but all large coarse growing weeds of these and other kinds, should be removed or kept well under, and that briars and brambles, if they appear, should on several accounts be grubbed up and destroyed. Ivy, too, as clasping, confining, fretting, and injuring the plants on which it rises, should be early cleared away to prevent the mischief of its after removal.

It is hardly necessary to observe, as it must be evident, that this account is far from comprehending all the plants which have been considered as weeds by writers, and those engaged in the cultivation of land; as such as are known to be prejudicial or hurtful, in some way or other, to some sorts of cultivation or other, have, for the most part, been only introduced.

Those who may wish for further information on the subject, may consult the paper on weeds, by Mr. Pitt, inserted in the fifth volume of "Communications to the Board of Agriculture;" and also the new edition of Miller's Dictionary, by Martyn, in which a very large catalogue of weed-plants is given; as well as many of the Corrected Reports on the Agriculture of different Counties.

It is remarked by the writer of the above paper, that the

plants we term weeds, considered as respecting mankind, are not totally useless; many of them have valuable medicinal, and, perhaps, other qualities and properties, and some of them may be applied to uses so as to pay something towards the expence of clearing them from the ground: thus, low-thistles are good for rabbits or hogs, the hog-weed is useful for either pigs or cattle: horses are said to be fond of young thistles when partially dried, and the seed may be prevented from spreading by gathering the down, which makes good pillows; however, there is some danger in trusting them to this stage of growth, as a high wind would and frequently does disperse them over a whole country, as has been seen already. Chadlock, when drawn, may be given to cows, who are very fond of it; and it is said in the Oxford Report on Agriculture, that it can be converted into good hay. Further, that nettles, fern, and the more bulky hedge-weeds, may be collected and annually burnt, as has been seen above; their ashes being afterwards formed into balls, which are of considerable value, as being used in composing a ley for scouring and cleaning linen and other cloths.

It is stated, too, that pigeons are of use in picking up the seeds of many weeds that would otherwise vegetate; and the writer has no doubt but that a prodigious quantity of the seeds of weeds are eaten by different sorts of small birds, particularly of those of most of the lake-weeds, of spurry, and in severe weather, of the different sorts of chadlocks, as well as of many other kinds. But that it has been observed, that bees have not thriven or done so well in this country since the extirpation of weeds has been more attended to, and become more general.

It is noticed, that in Japan, and in China, not a weed, it is said, is to be seen; and that they make use of night-soil only as a manure, partly with the view of preventing any risk of weeds being produced in that way.

In concluding, it may be noticed, too, that the same writer has remarked, that the vegetables we term weeds are more hardy and tenacious of growth than any others; nor can it indeed be otherwise than that those plants, which succeed in spite of opposition, must be of the most hardy kind. But that the production or growth of weeds is equally consistent with the divine goodness with that of the most valuable plant, for myriads of diminutive creatures, enjoying life and animation, are fed and supported by them, and to whom they are a more natural prey than the dietetic plants of mankind: and that man, possessed of reason, reflection, and intelligence, has powers and abilities to select and cultivate such vegetables as are adapted to his use, and proper for his sustenance, and to destroy and extirpate others; and thus to appropriate to himself what proportion he may think proper of the earth's surface; which if he should neglect to dress and cultivate properly, it will, in some degree, revert to its natural state, producing the hardier and more coarse and acrid plants for the sustenance of numberless tribes of insects and other little animals, and for an infinity of other known and unknown uses and purposes; and that indeed were it otherwise, the indolence of the human race might, in some measure, suspend the bounty of providence, and the fertile parts of the surface of the earth, instead of being covered with an universal verdure, would, by inattention or neglect, be rendered little different to the sterile and barren desert.

WEED, *Dyer's*. See DYER'S *Weed*, *Bastard* ROCKET, and WELD.

WEED, *Fuller's*. See TEAZEL.

WEED-HOOK, in *Agriculture*, a very useful implement for cutting up thistles, and other strong plants of the same nature;

ture; but as thistles, when cut either at an early period of the season, or before much rain falls, are apt to spring up afresh, and produce four or five stems in place of one; they should, perhaps in every instance, be pulled up by the roots, or, if they be cut, the operation should be done with a chisel within the ground, which is formed with a division in the mouth of it, so as to seize the stem part of the plant, and cut it deep down. See *WEEDING Dock-Spit*.

WEED, Silver. See *CINQUEFOIL*.

WEEDA, in *Geography*, a town on the E. coast of the isle of Gilolo. N. lat. $0^{\circ} 15'$. E. long. $127^{\circ} 45'$.

WEEDL, a town of the duchy of Holstein; 7 miles S.S.W. of Pinneburg.

WEEDING, in *Agriculture and Gardening*, the operation of freeing crops of any kind from noxious weeds. On the indispensable necessity, and great utility of this practice, it is altogether needless to enlarge. See *WEED*.

There are obviously two different methods to be principally employed in the removal and destruction of weeds; one of which occurs in the preparation of the land, and the other during the growth of the crop. In the former method it is necessary that such weeds as are of the root kind should be distinguished from those of the seedling description, as the destruction and removal of them must be effected in different ways, and upon different principles.

Weeding in garden-grounds is always a business that should be regularly and well performed in both the circumstances above-mentioned. Much may be frequently done in the former case by properly ridging or laying up the ground before the severe winter-season sets in, and in reducing and breaking it down in the early spring or other time, for levelling it, and making it ready for putting in the necessary crop, as the root as well as the seedling weeds may be greatly extirpated and destroyed in these different operations; the former affording the ready means of taking out the first sort, and the latter by putting them in the sprouting state, giving the opportunity of destroying the other. In the latter case, a great deal will be effected by the steady and repeated application of the hoe while the crops are upon the ground; and by good and careful hand-weeding, before the weeds have had time to ripen and shed their seeds.

It has been remarked with great truth, in regard to the extirpation and prevention of garden-weeds, that many will almost constantly appear, from the seeds being brought by the wind; as well as by being introduced by using raw dung, particularly of hogs and horses, which often contains seeds possessing their vegetative power, and the litter intermixed therewith not unfrequently containing more; which strongly shew that raw dung is very improper for gardens, though often used, particularly for early and other potato-crops, as it causes much trouble and expence in weeding.

Much labour in weeding must necessarily be saved, too, by drawing up all seedling weeds in time, as they appear, and before they have sown their seeds.

The extirpation and removal of weeds from garden-grounds are somewhat differently effected in various places: in some they principally use the spade, and the three-pronged or fanged fork, for cleaning out root-weeds; but the different kinds of hoes are employed for other purposes, of which the common ones are mostly made use of for scuffling over the surface, and those of the triangular and parallelogramic form, for cutting up weeds, moulding up and clearing growing plants, and loosening the surface of the ground for promoting the sprouting of any seeds that may be present, and other such uses. With these the scuffle or scuffler is sometimes had recourse to for cutting the weeds,

and working the surface of the land over in large gardens. In the small planted broad-cast sown crops, the weeding can only be well accomplished by performing the work by the hand. See *HOE, FORK, SPADE, SCUFFLE, &c.*

In regard to destroying and removing weeds in tillage-lands, it has been well observed by Naismith, in his "Elements of Agriculture," that when the ground is greatly overrun with weeds, a complete winter and summer fallow will, for the most part, be found unavoidable, in order to get entirely quit of them. Rib-fallowing, before the winter sets in, will, it is said, prepare the soil for parting freely with the vivacious roots, the ploughing and harrowing requisite to tear them up when the spring drought commences, will pulverise and reduce it, and provoke the dormant and inactive seeds to vegetate with the first moisture; by repeated turnings, during the summer, the greatest part may be made to vegetate, and be destroyed as they rise; and the vivacious roots, which lie beyond the reach of the plough, by being long prevented from exercising their vegetating powers, will be impaired in vigour. When winter-wheat, or any crop which is to stand through that season, is intended to be put in on such ground, it would be proper that the seed should be sown in drills, that by stirring the intervals in the ensuing summer, the tendency which moist soils have to condense or consolidate too much when greatly pulverised or reduced in their parts, may be counteracted. If spring-feed be intended, the last ploughing should be given to the land before the winter's rain commences, and the field be accurately and fully surface or furrow-drained, and laid dry. The influence of the atmosphere during the winter will, by these means, communicate the happy medium of consistence, on which so much depends; and the soil, as soon as it gets dry in the early spring, will be in the best order for the reception of the seed at that time, and the weeds the most fully and effectually destroyed and removed.

But where ground has been under any tolerable management, drill culture will, it is said, for the most part, suit all the purposes of a clean fallow, or be the means of rendering the land wholly free of weeds. In repeatedly turning the intervals, most of the annual weeds may be attacked in the group, and be expeditiously destroyed as often as they spring up; and the roots of the perennial ones be turned up and exposed to the heat and drought, which, if not altogether extirpated, will have their progress checked and prevented. But the rows should also be hand-weeded, and the hand-hoe will not unfrequently be found an important implement in this work. Drill culture may thus be partially exercised, in this intention, it is thought, every where with great advantage, adapting the application to any particular situation or circumstances. For example, where alternate courses of tillage and grass crops are adopted, in a course of three years' tillage, the second might always be in the drill manner; or if there were manure to spare, to keep a field in good condition in tillage-crops for four years, both the second and third might be in the drill method: the first on account of the tough turf or sward; and the last for the sake of sowing the land down with grass-seeds would be more convenient in the broad-cast state: but the weeding in these cases should not be neglected; the larger weeds especially; and all those which are most prevalent, and most productive of seed, should be taken out by hand labour, or some such means, when they begin to flower. By such strict care and attention to weeding tillage-land and crops and stocking the ground with proper perennial grasses when laid to rest, weeds would at length be so much subdued, it is supposed, as to be seldom injurious to the farmer.

The

WEEDING.

The writer of the paper on weeding has stated, that it is remarked by the author of the *Essays on Rural Affairs*, that there is only one mode of extirpating annual weeds, the seeds of which are indestructible; which is to put the ground into such a state as to induce them to sprout or germinate, and then to destroy the young plants by harrowing them up, or ploughing them under. This, it is believed, is strictly true; but the author of the paper just noticed does not exactly agree with the writer of the essays in the process to be pursued for the purpose; the ground, in this intention, in his opinion, should be ploughed before winter, but not harrowed, it being better to lie rough through that season, so as to have the greatest extent of surface possible exposed to the action and mellowing effects and influence of frosts; that, as soon as it becomes dry, in or about March, it should be cross-ploughed and harrowed well down; many of the seeds and roots will then vegetate, which should in due time be ploughed under, and the land harrowed again, and this sort of process be repeated as often as necessary: this, it is said, is the true use and manner of summer-fallow in this view, which, to have its full and proper effect, should always, it is thought, be attended to early in the season, when the powers of vegetation are the greatest, and the heat of the sun is powerful; as under such circumstances the greater number of weeds will be brought into a state of growth.

It is thought that the great defect in the management of summer-fallows in the intention of destroying weeds would seem to be the neglect of working them early in the season, by which omission the vigorous annual seedling-weeds are not brought into vegetation in due time; as, after which, they will not grow until the spring following, when they appear in such abundance among the wheat or other crop, as sometimes to choke it up: this is the reason, it is said, why the field poppy, the corn-crowfoot, the tare, and many other annual weeds, make such havoc among wheat, when by a proper and judicious early working of the fallow, they might have been brought to exhaust themselves in the following summer: this appears very clear from the effect, for if no wheat were sown, the seeds of these weed plants would often fill the ground with a full crop; but seeds can vegetate but once, consequently had this vegetation been brought on in the fallow, and the plants afterwards been ploughed under in due time, none could have appeared in the wheat-crop.

It is supposed, too, that the turnip-culture is peculiarly adapted to the destruction of weeds, as for this sort of crop the ground must of necessity be in early and fine preparation, by which weeds of early growth are conveniently brought into vegetation, and destroyed; and those which remain in the living state in the soil may be exterminated by hoeing. It has been observed by the writer, that wet weather is as necessary as dry to give a summer-fallow its whole effect; for without a soaking of rain after the land is pretty well pulverised, numbers of the seeds of weeds will not vegetate, but remain and grow amongst the crop; the root-weeds are therefore to be destroyed in dry weather, and the seedling ones after rain; and though the land should, after a dry season, be apparently in excellent order for sowing, it will be better to wait the effect of rain, and even give time for the seedling weeds to vegetate, before the seed for the crop be actually sown.

It is, therefore, suggested, that the destruction of root weeds, and those of the seedling kind, on corn-land, must be effected upon different principles, and in different manners; the former, by working them out of the soil in dry weather only; the latter, by pulverising and reducing the particles of the soil, so as to induce the seed to germinate

and spring up fully after rain, and afterwards ploughing under the young plants: also that frequent ploughings and harrowings are necessary, to expose all the seedlings contained in the soil to the powers of vegetation. But it is conceived, that the ploughings and harrowings of fallow ground should not, however, immediately succeed each other; time should be given for the consolidation of the soil, which, after well harrowing, will undergo a slight fermentation, and settle, as it were, into a mass; after which it will turn up mellow, and the destruction of weeds will go on apace. It is thought, that the frequent ploughings, which have been recommended by some, are not only unnecessary, but injurious. It has always been observed, that one ploughing of a fallow too soon succeeding another has no other effect, when used in this intention, than that of rooting about the clods, and preventing the general effect of consolidation and fermentation in the land. The suffering of the weeds to spread their leaves a little between the several ploughings of a fallow, for this purpose, is not, it is supposed, injurious: care, however, must be taken not to carry this notion too far, particularly in the case of squitch or couch grass, or so as to suffer any of the quick growing weeds to ripen their seeds, or the luxuriant ones to become too large for being buried with the plough. As these remarks are judicious, and perfectly practical, they deserve the particular attention and consideration of the farmer, wherever the weeding and proper cleaning of his ground is concerned.

It is stated too, that in this view, if a fallow for turnips be cross-ploughed and harrowed down in the month of March, it will generally lie very well to the beginning of May; and that in general no fallow will want ploughing oftener, in such intention, than once in six weeks, if sufficient harrowings be given between the ploughings. The particular time most proper for these operations must, however, be determined not by any general rule, but by local circumstances, experience, and observation.

In cases where lands have not undergone proper improvement, or been under a bad state of management, weeds cannot be destroyed without much labour and expence. (See WEED.) But where lands are already improved, and have been for some length of time under a good system of management, the business is in part performed, and the evil much lessened; as in such cases, as well as all others, every rotation or course of cropping should render the land cleaner and freer from weeds, which will certainly be the case, where there is a proper and correct attention bestowed on the business. The means which are necessary to be used in this intention are commonly, it is said, these: complete and well-managed fallows, as above, when fallows are necessary or proper; the use of manures, which are free from the seeds or quick roots of weeds; the careful choice of such seed grain as is clean; the practice of short tillages, or that of not taking too many crops in rotation; the having recourse to attentive weeding and a spirited use of the hoe, in which view the drill husbandry doubtlessly, it is supposed, affords superior advantages to the broad-cast, in keeping land clean from weeds; but that land must be well cleaned before the drill husbandry is applicable; the plentiful use of the clean seeds of the best grasses and trefoils at the end of the tillage, in each case; the weeding of the land, when in or at grass, so as not to suffer the seeds of any noxious or injurious plants to spread themselves; and that when upon again breaking up the land, to pursue such a system or plan of cropping as will not increase or encourage weeds. But though much might be said on each of these points, it is thought unnecessary, as the intelligent farmer will readily

adopt every necessary regulation and precaution from his own observation and experience. It will, therefore, only be needful to slightly touch upon the different particulars or objects. As the subject of fallows has been already considered and explained, it is unnecessary to be further noticed in this place. In regard to fold-yard manure, it should always, it is supposed, in this intention, undergo a fermentation before it is laid upon the land, sufficient to prevent the future vegetation of any seeds that may be contained in it: but it should likewise be kept as free as possible from the seeds of weeds; and perhaps it is best laid on grass-land, applying only lime, or other manures certain of being clean, to fallows; or if dung not certainly clean from seeds be laid on fallows, it should be applied on them early enough to give time to have the seeds to vegetate and spend themselves before sowing for the crop. It is said, that every one knows the necessity of clean seed-corn to the producing of a clean crop, but sometimes neglects to apply such knowledge; and indeed clean seed-grain is not always to be procured. If weed-seeds be suspected, they should, as often as possible and practicable, be dressed out before sowing the corn. The weeding of crops is generally imperfectly performed, and is likely to continue so, it is thought, in many places, on account of the difficulty of procuring hands enough for work which is only so temporary in its nature. Thistles are generally only cut off, but they should always, it is said, by drawn up by tongs, or other tools for the purpose, and the other sorts of weeds by the hand. The hoe has yet been only of general use in turnip crops, nor is it likely to extend further, unless the drill husbandry should be more established; nor even, in its present application, can proper hands enough be always, it is said, procured at sufficiently reasonable rates. As much, however, should constantly be done in all these ways as circumstances will allow. In the laying down of land to grass, the importance of clean grass-seed is well understood; yet the seeds of docks are not unfrequently sown with clover, and those of other pernicious weed-plants with ray-grass. In all cases, the utmost attention should be paid to the sowing of clean seed of this small kind. And in the weeding of grass-land, docks and thistles are often mown, or only cut off, but they should always be rooted up; for which purpose, docking irons formed upon sufficiently good principles are mostly had recourse to. They are, it is supposed, every where well understood, consisting simply of a forked or cleft spike of iron, which is jogged within the cleft, and fixed to the end of a wooden lever: this being forced down by the hand or foot, so as to inclose the root of a dock, or large thistle, will easily bring it up, particularly after rain; but mowing them off, being done with more expedition, is often practised; and they are sometimes left undisturbed, and suffered to scatter their seeds without any effort being made to prevent it, which is very injurious, and always to be avoided as much as possible. It is stated too, that upon breaking up a turf or sward, it is understood in the writer's neighbourhood, that unless a wheat fallow or a turnip crop compose a part of the tillage, the land will be injured, and rendered fouler, and more addicted to produce weeds: this notion is, it is believed, a just one, though often deviated from in practice, for the sake of present profit, and under the delusive idea of cleaning the land again next tillage. It is, however, well ascertained, that land well cleaned by former good management will best bear this deviation; for the fewer weeds it contains at breaking up, the less will be the increase of them during the tillage or after-culture of the ground.

The writer of the Elements of Agriculture noticed

above has observed, that it is not enough to attend to weeding in the time of tillage-culture only: it is proper that grass-fields and lands should likewise be kept free of all noxious, hurtful, and unprofitable herbage. The negligence which may be seen in this respect, in many districts and places, is, it is said, shameful. Pastures and other grass-lands are sometimes so close covered with large weeds, that the pasturing animals have scarcely room to pick up a mouthful; and thus the vegetable food and other matters, which should nourish good and wholesome pasture and other grass-land herbage, is consumed by useless weeds. And speaking of different coarse and disgusting weed-plants, such as the dock, ragweed, bur, corn, and sow-thistles, and some others, it is remarked, that the two last are of the sort which extend their vivacious roots below the reach of the plough, when the land is in tillage. It is not, it is said, uncommon with those who affect to pay a little more attention than ordinary to their pastures and grass-lands, to cut down these plants in the flower. If this be done in a rainy time, or if such rain falls soon after, the water descending into the fresh cut wound of the stem, debilitates the roots, and discourages the growth of the plants for a time, though they are seldom wholly destroyed by it; but that if such critical rains do not occur, fresh leaves immediately arise to support the roots, and the cutting over has very little or no effect. They should consequently be annually pulled up by the roots as soon as possible, after the flower begins to form and shew itself, taking advantage of the first shower which happens to fall, to soften the ground and make them draw up more freely. By pursuing this practice regularly and steadily for a number of years, the deep lying perennial roots are, it is said, gradually weakened, and fall into decay. Nor is cutting down the ragweed of much avail. Some of the plants die, but many survive, and branch out more copiously the ensuing year. But this plant not being deep-rooted, is easily pulled up when in flower, if the ground be soft at the time. The bur-thistle being a biennial plant, may be killed at any time by cutting it under the first leaves. The common dock is the most troublesome plant in grass-land, especially in clayey soils, where it is always the most frequent. Every bit of its long tap-root left in the ground will continue to vegetate and grow, and at length form a new stem and plant. It should, in all cases, be fully turned out with the dock-iron, in the manner already noticed, as soon as the flowering-stem is formed; and as the plants of this kind rise at two seasons, the pasture or grass fields should be weeded twice in the summer, that no seeds may be allowed to ripen. The roots should be fully exposed to the heat and drought; for if they be in a moist place, they will continue to vegetate on the surface, as they lie and strike out side-roots into the ground. All other inesculent herbage on pastures and other sorts of grass grounds, and all weeds bearing seeds by the sides of roads, ditches, brooks, and other such places, should be cut down too, when they begin to flower, in order to prevent their increase by their seeds being dispersed over the grass fields and grounds.

The writer of the Gloucestershire Report on Agriculture, in reproaching the practice of confining the business of weeding almost solely to the tillage-lands, while the meadows and pastures are almost wholly neglected, and overrun with docks, thistles, nettles, hemlock, and many other such weed-plants, remarks, that it is supposed by the farmers, that the scythe will be early enough to cut them off: the seeds, however, are generally ripened and dispersed before mowing time; and if not, they are carried with the hay to the stall, and mixed with the dung, or into the pasture

WEEDING.

ture for fodder during the winter; in either of which cases they cannot fail, it is supposed, of increasing greatly. Besides, the mere cutting off this kind of weeds rather improves than diminishes their growth, by forcing them to throw out new shoots from the roots, and that in greater abundance than before. Thus, a thistle, which rises at first with a single stem, if cut off above the surface of the ground, spreads with several lateral branches, and covers a large space of ground. The most likely method of destroying them is to draw them up by the roots, as already seen, which may easily be done when the ground is moist, and is done by those farmers there, it is said, who are anxious for their credit, nice in their herbage, and proud of seeing their pastures rivalling the neatness of a lawn. The negligence, indeed, of a neighbour often operates as a discouragement, and it is an evil not easily to be prevented: it is, however, surprising in another instance, it is said, to observe an almost unanimous encouragement given to the multiplication of noxious weeds. In the highways they are left to grow to maturity, and their seeds are dispersed in immense quantities in every direction, and all over the country, by the wind, or by being carried by birds. Under these circumstances, it is said to be certainly of little use for one, or even all the occupiers of ground, to clear their lands of weeds, while this plentiful source of them remains unmolested. One should suppose, the writer observes, that the evident mischief resulting from this neglect would excite a general combination against these destructive enemies to the interests of agriculture: that, however, not being the case, might it not, it is asked, be convenient to incorporate with the duty of the surveyors, or overlookers of the roads, the business of cutting up, and otherwise destroying, such kinds of weeds within their districts or boundaries? Should the fact of the thousand-fold increase of such self-sown seeds be doubted or disputed, let, it is said, any one but observe a patch on a common, from which the turf or sward has been pared, how completely it will be covered with thistles in the following summer; and the arable fields adjoining are not much better, where this negligence prevails.

And the writer of the paper on the subject of weeding states, that there is another cause of the increase and propagation of weeds, which may be termed a *public* cause, and which it is not in the power of any individual to prevent; but which a slovenly, neglectful, or ill-disposed person may promote and increase, and which can only be effectually prevented by a *political* regulation, and for which, it is believed, no provision has yet been made in our political code: thus are the numbers of vigorous and luxuriant weeds which are suffered to ripen their seeds in our hedges, pastures, woods, and other lands, and the seeds of which being provided with feathery matters, are dispersed over the whole territory of the kingdom, and propagate themselves far and near, growing in whatever places they alight and settle, and producing a most abundant crop: the most common and pernicious of which are supposed to be the different sorts of sow-thistles, sow-worts, common thistles, colt's-foot, groundfels, knap-weeds, &c. For as the seeding and scattering of the seeds of all these sorts of plants is clearly a public nuisance, and as they are subject to be carried to a great distance by the above means, and to do harm to the lands of all occupiers indiscriminately, they should, it is thought, be under the controul of our political regulations. This would be the effectual means of preventing much labour and expence to the farmer and the occupier, in the weeding of different kinds of lands and crops, and at the same time go a great way in rendering the territory of the country ultimately clear of a great proportion of its most noxious and hurtful weeds.

Besides, regulations of the above kind have been applied in different countries and places to weed-plants, which are much less injurious and hurtful than these. See *WEED*, and the above paper in the fifth volume of Communications to the Board of Agriculture.

In some cases and parts of the country, the weeds in the lefts heavy tillage-lands are destroyed, by an entire and perfect summer-fallow every third year, which is an effectual but expensive method of proceeding; but on the strong loams and other heavy soils by good hoeing and hand-weeding the drilled or set crops of beans, peas, and some other kinds. On the sandy and other light loams, by well hoeing and weeding by hand the crops of peas, potatoes, turnips, and some others. As soon as the peas or tares are off the land, the ground is ploughed and well harrowed, and the root-weeds picked or raked together, and burned or otherwise disposed of, as noticed above; which is mostly repeated after the cross-ploughing and harrowing have been performed. The ground being then in a great measure free from root-weeds, the turnips are sown, and the seed-weeds that may arise destroyed by twice or oftener hand-hoeing and weeding. This sort of practice being repeated or put in execution once in three or four years, is capable of keeping light land tolerably clean and free from weeds. However, in the case of a hot dry summer, the labour and expence of raking, collecting, picking, and burning the weeds, may not unfrequently be saved, and the roots destroyed, by only harrowing them to the surface after every ploughing; and by that means exposing them well to the heat of the sun for a sufficient length of time to kill them, which is sometimes effectually done in the course of a week. Care must, however, always be taken that they are fully and completely destroyed, otherwise much mischief may be the consequence, as they are extremely tenacious of life.

In all cases, where the staple or vegetable mould of the soil is of a sufficient depth to admit of trench-ploughing, that sort of ploughing, with the assistance of heavy rolling, and other proper means, will in some circumstances completely destroy root-weeds. In some cases, it is even more effectual for that purpose, it is said, than any greater number of ploughings, and is an excellent method, where it can be accomplished without turning up a poor barren subsoil. The great utility and importance of it in cleaning garden-grounds have been already seen, and it is supposed to be equally beneficial in destroying weeds, and preserving the soil moist in the most drying weather of the summer season. See *TRENCH-Ploughing*, and *TRENCHING*. Also *RIDGING-up*.

The work of weeding in all cases should be begun sufficiently early in the spring, that the weeds may not be in too forward a state, and the business, in whatever way it is undertaken, be effectually and completely performed, without any sort of omission or neglect. In the meadows and pasture-lands it should be equally attended to as in the corn-fields, as in all situations weeds are a very great drawback upon the farmer's profit, and of vast inconvenience in many different ways.

It is presumed by the writer of the paper on weeding, that if the above proposed regulations, precautions, and methods of destroying injurious plants were generally adopted in practice, they would render the British empire as free from weeds as those of China and Japan.

It may be concluded that, on the whole, by great, unremitting, and proper attention, with some such regulations as the above, to the extermination and destruction of all sorts of useless and hurtful weeds in cultivated grounds, and from meadows and pastures, the growth of injurious and worthless plants may be prevented, and the arable crops be rendered

dered much more abundant and productive than they usually are, and those of the grass kind be provided with a better and more useful herbage for the support of live-stock of all kinds, which would greatly contribute to the farmer's profit and advantage.

WEEDING-Chisel, in *Agriculture*, an useful tool with a divided chisel point for cutting the roots of large weeds within the ground. See **WEED-Hook**.

WEEDING Dock-Spit, the tool used in extirpating weeds of the dock, thistle, and other such large kinds which are to be got up by the roots. It is a sort of crow or lever, with a claw at the bottom end of it, a little curved forward, and divided into two side parts, in somewhat the manner of the thin end of a common hammer used for drawing nails: it has an arm or tread which projects at about eight or ten inches from the lower end, for the foot to rest firmly upon in forcing it into the ground, and at a little distance above it, on the back side, a curve of iron, projecting about three inches; on the upper or top end, a handle is fixed, and fastened as in the common spade: in using it the claw seizes the root of the plant, and, by a gentle pressure of the handle end downwards, in the manner of the lever, easily and readily draws or forces it out of the ground: by means of this simple implement or contrivance, many hundreds of such weed-plants may be eradicated or drawn out in the course of a day. It has sometimes the names of weeding-spud or spade, and dock-spit or spud given it. See **WEEDING**.

WEEDING-Forceps, or Tonges, the tool of the nipper kind, which is made use of for taking up some sorts of plants in weeding corn and other crops, such as small thistles of different kinds, small docks, and various other such weeds. It seizes them by the mouth part, which is fixed upon them by means of the long handles in using it, and readily forces them up. See **THISTLE-Drawer**.

WEEDING-Fork, a strong three-pronged fork of the fork sort employed for working root-weeds in tillage-lands, and forking out the weeds of the same kind in garden-grounds; in both which cases it is a very useful and effective tool. It is sometimes made with flat prongs, and termed a spud in plantation-grounds. See **FORK**.

WEEDING-Shim, an implement which is constructed differently to suit different purposes, but that which is made with a frame somewhat like that of the common wheelbarrow, is considered the best in the county of Kent, where tools of this sort are much used in the plantation-grounds for different crops. It is a very useful and convenient tool for the purpose of tearing up weeds on summer-fallows, and in many other cases. Its cheapness too is a great recommendation of it, as it is capable of being well constructed for about two pounds. See **HARROW**, &c.

WEEDING-Spud. See **WEEDING Dock-Spit supra**.

WEEDS, in *Mining*, a term used by our English diggers to express any sort of unprofitable substance found among the ores of metals. They seem to have borrowed the phrase from the gardeners; and as every thing with them is a weed, except what they have planted, and expect to gather, so every thing is a weed with the miners, except the thing they are sinking for. See **DIGGING**.

The principal substances known in our mines under the name of weeds, are mundic or marcasite; this is of three sorts, white, yellow, and green; daze, a kind of glittering talky stone, of the telaugium kind, which endures the fire, and is of various colours and hardnesses; iron-moulds, or pyritæ; caul, which is brownish and spongy; and glister, which is a sort of talc. Phil. Trans. N° 69.

WEEDS also denote a peculiar habit, worn by the relicts of persons deceased, by way of mourning. See **MOURNING**.

WEEK, *Septimana, hebdomada*, in *Chronology*, a division of time, comprising seven days.

The origin of this division of weeks, or of computing time by sevenths, is greatly controverted. Some will have it to take its rise from the four quarters or intervals of the moon, between her changes of phases, which, being about seven days distant, gave occasion to the division. Be this as it will, the division is certainly very ancient. The Syrians, Egyptians, and most of the oriental nations, appear to have used it from all antiquity: though it did not get footing in the West till Christianity brought it in: the Romans reckoned their days not by sevenths, but by ninths; and the ancient Greeks by decads, or tenths.

Indeed, the Jews divided their time by weeks, but it was upon a different principle from the other eastern nations. God himself having appointed them to work six days, and to rest the seventh, in order to keep up the sense and remembrance of the creation; which, being effected in six days, he rested the seventh.

Some authors will even have the use of weeks, among the other eastern nations, to have proceeded from the Jews; but with little appearance of probability. It is with better reason that others suppose the use of weeks, among the heathens of the East, to be a remain of the tradition of the creation, which they had still retained with divers others.

This is the opinion of Grotius, *De Veritat. Relig. Christi*. lib. i., who likewise proves, that not only throughout the East, but even among the Greeks, Italians, Celtæ, Sclavi, and even the Romans themselves, the days were divided into weeks; and that the seventh day was in extraordinary veneration. This appears from Joseph. *adv. Apion*. II. Philo. *de Creatione*. Clem. Alexand. *Strom.* lib. v. Though Helmoldus, lib. i. cap. 84. Philostratus, lib. iii. cap. 13. Dion. lib. xxxviii. Tibullus, Lucian, Homer, Callimachus, Suetonius, Herodotus, &c. who mention the septenary division of days as very ancient, suppose it to have been derived from the Egyptians.

The *days of the week* were denominated by the Jews, from the order of their succession from the sabbath. Thus, the day next after the sabbath, they called the *first* of the sabbath; the next, the *second* of the sabbath; and so of the rest; except the sixth, which they call *parasceve*, or preparation of the sabbath.

The like method is still kept up by the Christian Arabs, Persians, Ethiopians, &c. The ancient heathens denominated the days of the week from the seven planets; which names are still generally retained among the Christians of the West. Thus the first day was called *Sun-day*, *dies solis*; the second *Moon-day*, *dies lune*, &c. a practice the more natural on Dion's principle, who says, the Egyptians took the division of the week itself from the seven planets.

In effect, the true reason of these denominations seems to be founded in astrology. For the astrologers distributing the government and direction of all the hours in the week among the seven planets, ♃ ♄ ♂ ♁ ♀ ♃ ♄, so as that the government of the first hour of the first day fell to Saturn, that of the second day to Jupiter, &c. they gave each day the name of the planet, which, according to their doctrine, presided over the first hour thereof; and that, according to the order specified above; and which is included in the following technical verse.

Post SIM SUM sequitur, pallida Luna subest.

Wherein, the capital letters SIM SUM, and L, are the initial letters of the planets. So that the order of the planets

planets in the week, bears little relation to that in which they follow in the heavens: the former being founded on an imaginary power each planet has, in its turn, on the first hour of each day.

Dion. Cassius gives another reason of the denomination, fetched from the celestial harmony. For it being observed that the harmony of the diatessaron, which consists in the ratio of 4 to 3, is of great force and effect in music; it was judged meet to proceed directly from Saturn to the Sun; because, according to the old system, there are three planets between Saturn and the Sun, and four from the Sun to the Moon.

Our ancestors the Saxons, before their conversion to the Christian faith, named the seven days of the week from the Sun and Moon and some of their deified heroes, to whom they were peculiarly consecrated, which names we received and still retain: thus Sunday was devoted to the Sun; Monday to the Moon; Tuesday, according to some, to Tuisto or Tuisco, mentioned by Tacitus; but, according to others, to Thyfa or Dyfa, the wife of Thor, and the goddess of justice; or, according to others, to Tyr; Wednesday to Woden, the god of war; Thursday to Thor, who presided over the air, and was supposed to govern the winds and clouds; this is the same with Lucan's Taranis, similar to the Welsh word for thunder; Friday to Friga or Fræa, the wife of Thor, and the goddess of peace and plenty; and Saturday to Seater, called also Orodo, to whom they prayed for protection, freedom, and concord, and for the fruits of the earth. The origin of the last appellation, however, is doubtful; as some have observed, that the name *Seater* is not mentioned by any writer before *Verftegan*. See *Verftegan's* Restitution of decayed Intelligence, p. 68. Junii Etym. Angl. and Mallet's North. Ant. vol. i. p. 91, &c.

To find the accomplishment of Daniel's prophecy of the Messiah, the destruction, rebuilding, &c. of the temple, chap. ix. ver. 24, &c. the critics generally agree to understand *weeks of years*, instead of *weeks of days*.

Accordingly, Dr. Prideaux, fixing the end of these weeks at the death of Christ, in the year of the Julian period 4746, and in the Jewish month Nisan, dates their commencement in the month Nisan, in the year of the Julian period 4256, which was the very year and month in which Ezra had his commission from Artaxerxes Longimanus, king of Persia, for his return to Jerusalem, there to restore the church and state of the Jews. And thus he finds, that from the one period to the other, there were exactly 70 weeks of years, or 490 years. Connect. vol. ii. p. 381, &c.

WEEKS, *Ember*. See EMBER.

WEEKS, *Feast of*. See PENTECOST.

WEEK, *Passion*, or the *Holy Week*, is the last week in Lent, in which the church celebrates the mystery of our Saviour's death and passion.

This is also sometimes called the *great week*. Its institution is generally referred, both by Protestants and Papists, to the times of the apostles. All the days of that week were held as fasts: no work was done on them; no justice was distributed; but the prisoners were ordinarily set at liberty, &c. even pleasures, otherwise allowed, were at this time prohibited. The osculum charitatis was now forborn: and divers mortifications practised by all sorts of people, and even the emperors themselves.

WEEK, *Rogation*. See ROGATION.

WEEK, or *Wick of a Candle*, &c. the cotton match in a candle or lamp. See CANDLE, LAMP, &c.

WEEK-Fish, in *Ichthyology*, a name given by some to a

very delicate fish, caught on the East Indian shores, and called by the Dutch there the *wit-visch*. See WIT-Fish.

WEEKLY *Markets and Fairs*, in *Agriculture*, are of considerable use and convenience to the farmer and land-owner, as affording the ready means of purchasing, providing, and furnishing them with the different articles they are continually in need of, as well as the various fairs and descensions of cattle and other live-stock, which are always wanted in such cases; as they are common in most large towns, the former once or oftener in the course of the week, and the latter in some instances in that time, and at more distant periods. They give the means, too, of readily disposing of all sorts of produce and stock of the farm kind, which is often a very great accommodation and advantage to the farmer and store-master, as is fully seen in the weekly market of Smithfield in the metropolis, as well as in many particular markets and fairs in the country, as at Liverpool, Lancaster, Garstang, and many other towns in the north; and at Uxbridge, Reading, Chelmsford, Petworth, and a variety of other towns in the south. See Owen's Book of Fairs, &c.

WEELING, ANSELM, in *Biography*, born at Bois-le-Duc in 1675, was an imitator of Godfrey Schalken and Adrian Vanderwerf; but particularly of the former; and many of his productions have been taken for pictures by that master. He died in 1749.

WEELS, in *Geography*, a river of Germany, which rises in the duchy of Oldenburg, and joining the Ochte, in the county of Delmenhorst, falls into the Wefer, 8 miles N.W. of Bremen.

WEEN. See HWEN.

WEENINX, JOHN BAPTIST, in *Biography*, an excellent artist, was born at Amsterdam in 1621, the son of John Weeninx, an artist of considerable celebrity. He lost his father when he was very young, and was placed by his mother with a bookfeller; but his taste for painting manifesting itself decidedly, he was allowed to indulge it, and was placed as a disciple with John Micker, and afterwards with Ab. Bloemart. He made a rapid progress, and drew with superior power the principal buildings in Amsterdam and its vicinity. Animals, birds, huntings, &c. he was skilled in representing, and he soon began to paint his subjects with success. He left Bloemart, and studied a short time with Moojaert; but when he was 18, he found himself sufficiently established to trust to himself, and his pictures were favourably received.

A desire to improve led him to Rome, where his talents recommended him to many of the principal personages; among others, the cardinal Pamphili gave him a pension, and honoured him with many commissions: he would fain, indeed, have retained him at Rome, but the solicitations of his family, and his natural desire of exhibiting his power among his countrymen, induced him to return to Holland, after an absence of four years. On his return, he found abundant admiration and employment, which, indeed, he very well merited, as his extraordinary facility in painting a vast variety of subjects has rarely been equalled. He painted history, portraits, landscapes, sea-ports, animals, and dead-game; but he particularly excelled in Italian sea-ports, enriched with noble architecture, and decorated with figures. There is a very beautiful specimen of his power in the gallery of Cleveland-house, which in Britton's Catalogue is numbered 243. He unfortunately died very young, in 1666, being only 39 years old.

WEENINX, JOHN, son of Baptist, mentioned above, was born at Amsterdam in 1644, and was instructed in painting by his father until he was 16 years of age, when

he had the misfortune to lose that able instructor. His talent was not of so general a nature as that of his father; but in birds, flowers, animals, and fruit, he has seldom been surpassed for the boldness, animation, and correctness of touch, or the brilliancy and clearness of colour, as well as of chiaro-oscuro. The elector John William invited him to his court, and many of his most considerable productions are at the gallery of Duffeldorf. He decorated a hunting seat of the electors, the chateau of Benberg, with a series of hunting of the boar and the stag, in which he displayed his skill and taste with brilliant effect. His smaller works are exquisitely finished, yet with great breadth, and deservedly esteemed. He died in 1719, at the age of 75.

WEEPER, in *Zoology*. See *SIMIA Capucina*.

WEeping, in *Physiology*. See LUNGS and TEARS.

WEeping-Rock, in *Agriculture*, that sort of laminated, or porous, open rock, through which water passes in a slow, gradual, weeping manner. Strata of this kind are not unfrequently very troublesome in the practice of draining. See WALL-Spring and SPRING-Draining.

WEeping-Spring, that sort of discharge of water from the internal parts of the earth which is produced in a very slow weeping manner. The draining of springs of this sort is sometimes not attended with much difficulty, while in other cases they are often very troublesome. See SPRING and SPRING-Draining.

WEER. See WEIR.

WEERAWAU, in *Geography*, a town of Hindoostan, on the borders of the desert of Cutch; 40 miles W. of Buddakano.

WEERDT, or WERDT, a town of Germany, in the bishopric of Munster, on the Old Ifsel; 40 miles W. of Munster. N. lat. $51^{\circ} 52'$. E. long. $6^{\circ} 33'$.

WEERT, or WERT, a town of France, in the department of the Lower Meuse; 10 miles W. of Ruremond. N. lat. $51^{\circ} 17'$. E. long. $5^{\circ} 43'$.

WEERT, *Nieder*, a town of France, in the department of the Lower Meuse; 10 miles S.W. of Venlo.

WEESDALE, a town of the island of Shetland; 6 miles N.W. of Lerwick.

WEESSENSTEIN, or WESSENSTEIN, a town of Saxony, in the margraviate of Meissen; 5 miles S.W. of Pirna.

WEEVER. See WEVER.

WEEVER, in *Ichthyology*, the English name for the fish called by Willughby and other authors the *draco-marinus*, or sea-dragon.

Belon says, that this name is a corruption of the French *la vive*, because this fish is capable of living long out of the water.

Mr. Pennant describes another species, under the name of the *great weever*, the *draco major*, or *araneus* of Salvan, which inhabits the sea near Scarborough. Brit. Zool. vol. iii. p. 171.

WEEVIL, in *Natural History*, the name of a small insect which does great damage in magazines of corn, by eating into the several grains, and destroying their whole substance.

This creature is somewhat bigger than a large louse, and is of the scarab or beetle kind, having two pretty, jointed, tufted horns, and a trunk or piercer, projecting from the fore part of its head: at the end of this trunk, which is very long in proportion to its body, there is a sort of forceps or sharp teeth, with which it gnaws its way into the heart of the grain, either to seek its food, or to deposit its eggs there.

By keeping these creatures alive in glass tubes, with a

few grains of wheat, their copulation and manner of generation have been discovered. The female perforates a grain of wheat, and in it deposits a single egg, or, at the utmost, two eggs; and this she does to five or six grains every day, for several days together. These eggs, which are not larger than a grain of sand, in about a week produce as odd a sort of white maggot, which wriggles its body very much about, but is very little able to move from place to place: this, in about a fortnight, turns to an aurelia, from which is produced the perfect *weevil*. This destructive creature is itself very subject to be destroyed, and when in the egg or aurelia state, it is very subject to be eaten by mites. Baker's Microf. p. 221. Leewenhoeck, tom. iv. ep. 76.

It is stated in a series of communications which contain different interesting particulars, inserted in the appendix to the Corrected Report on the Agriculture of the County of Middlesex, that J. L. Banger, esq. of the island of Madeira, has found that steaming such grain as is infested with the weevil has the effect of preserving it. In comparing the method used by another person with his, on portions of the same cargo of grain, the quantity or weight was greater in the latter; but the most essential difference was in the quality, which in the former was almost unsaleable, while in the latter, or that of steaming, it was better and sweeter than when first received. The produce of grain from the island of St. Michael it is found cannot be preserved so long a time as that which is imported from any other country, though the manner of keeping it there, which might throw some light upon the subject, is not known: of this the writer has recently obtained sufficient experience, it is said, by having ordered a part of a cargo of grain to be placed in a store which had lately been used with that island wheat; and from this cause, in a very short time, had become badly infested with the weevil. Another purchaser of a part of the same cargo, too, is, from a similar cause, a sufferer. The writer has not, however, much anxiety about it, as the grain he purchased and steamed once on the first of January, and again on the first of June, is now, (the time of writing,) in perfect preservation, and free from the weevil. The Indian corn too, that was purchased then in March last, at which time it was very full of the insect, is at present free and perfect, it is said, without a second heating. It is intended passing it again through the steam, however, it is said, as soon as the apparatus is properly fixed, when no doubt is made of its keeping through the year. In examining the particular tendency that the grain lately arrived has to the generation of the insect, the writer has imagined it in some measure to proceed from the embargo laid upon American vessels having obliged the merchants in the different sea-ports to keep their granaries so full as to have heated the grain; though he has some reason to think that the months of March and September are attended with peculiar circumstances respecting the increase of the weevil.

It is found that by the consumption of one hundred pounds weight of coals in a kitchen portable steam apparatus, three moys, or seventy-two English bushels of grain can be steamed in the common hours of work of one day.

The writer had then lately steamed a granary of sixty moys, or one thousand four hundred and forty English bushels, in about three weeks. The waste of grain, not badly infested with the weevil, is found to be one per cent. in weight in one month, and the increase so rapid, that if proper precautions be not taken, in less than six it will be rendered totally unfit for use; and that in the West Indies the writer is satisfied from his own experience, that three months will be equal, in destruction to the grain, to that

that of six months in the temperate climate in which he writes. Perhaps, it is said, no part of the globe would experience so much benefit from the use of steam as a rice country.

The writer having, by substituting copper tubes for those of tin, which were at first employed, but tinned to prevent mischief, at last succeeded in getting them sufficiently tight, proceeded better in his trials: the steamed rice remained free from dust, and it is supposed that steam may be rendered very serviceable in separating the husk from the grain in that case, as well as in barley, &c.; nay, that it may be extended to flax, and many other articles.

The attention of the writer more lately has been particularly attracted, by finding some grain that had been steamed to grow, when sown, in repeated trials; and from the very flourishing state of what is come up, and his own observations, he is led to think that the blight in wheat might be materially prevented by having it steamed before it is sown. It was afterwards discovered that the flourishing condition of the wheat sown after steaming surprised every one who saw it; and it is thought to be an object worthy of consideration.

It was found, on taking a certain quantity of wheat that had been steamed, and of such as had not, and sending them to the mill, that there was an increase of nearly five *per cent.* in the bread produced from the wheat that was steamed: but it is not certainly known if this difference would have arisen, if the latter had been dried in the sun or an oven, as sometimes practised there, but which is troublesome. The best bread made there is, it is said, from a mixture of fine American flour and island wheat; and the writer has no doubt, that if a baker was to make use of steam, he might, in the proportion of wheat in the quarter loaf, save from five to ten *per cent.*

The writer intends to try the advantages to be gained by steaming seeds to be sent to foreign countries. Biscuit, he is convinced, may be kept any length of time by it; but from its size, the operation of steaming it is considerably more difficult than grain. Wheat provided in any way, in general, it is said, gets better and more free from the weevil by steaming. See the Paper.

The weevil, too, is said to be very injurious and destructive to the wheat and Indian corn in America, so that the means of preventing it must be of great utility and consequence.

WEFERLINGEN, in *Geography*, a town of Westphalia, in the principality of Halberstadt, insulated in the duchy of Magdeburg; 25 miles N. of Halberstadt.

WEFT, a kind of web, or thing woven; as, a *weft* or trefs of hair. See WEB, HAIR, TISSUE, &c.

WEFT, or *Woof*, the cross-threads of cloth. See WEAVING.

WEGELEBEN, in *Geography*, a town of Westphalia, in the principality of Halberstadt; 5 miles N. of Quedlingburg.

WEGERSDORF, a town of Prussia, in Oberland; 3 miles S. of Salfeldt.

WEGG'S ISLAND, a small island in Hudson's Bay. N. lat. 63° 20'. W. long. 90° 25'.

WEGG'S Lake, a lake of North America. N. lat. 50° 25'. W. long. 92° 25'.

WEGGIS, a town of Switzerland, in the canton of Lucerne, and capital of a bailiwick, situated on the north side of the Lake of Lucerne; 7 miles E. of Lucerne.

WEGSTADEL, a town of Bohemia, in the circle of Leitmeritz; 10 miles S.E. of Leitmeritz.

WEGSTAD, or VEGESTAD, a town of the bishopric of Passau, insulated in Austria; 12 miles E. of Passau.

WEHAX, LILL, and STOR, two small islands on the E. side of the Gulf of Bothnia. N. lat. 60° 45'. E. long. 21° 7'.

WEHEN, a town of the principality of Nassau Saarbrück Ufingen; 10 miles N.N.W. of Mentz.

WEHLEN, or WEHLAU, or *Wehl-Städtel*, a town of Saxony; 5 miles S. of Pirna.

WEHMALAIS, a town of Sweden, in the government of Abo; 20 miles N. of Abo.

WEHNER, a town of East Friesland; 13 miles S. of Emden.

WEHR, a river of the duchy of Baden, which runs into the Rhine, 4 miles W. of Seckingen.

WEHRENDORF, a town of Westphalia, in the county of Ravensburg; 5 miles W.S.W. of Vlothow.

WEHRENSSEE, a town of the duchy of Stiria; 6 miles N. of Luttenberg.

WEHRHEIM, a town of Germany, in the principality of Nassau Dillenburg; 18 miles S.S.W. of Dillenburg.

WEIBSTADT, a town of the duchy of Baden; 28 miles E.S.E. of Mannheim. N. lat. 49° 17'. E. long. 8° 59'.

WEICHOLTZHAUSEN, a town of the duchy of Wurzburg; 6 miles N.N.E. of Schweinfurt.

WEICHSEL. See VISTULA.

WEICHSELBURG, a town of Saxony, in the lordship of Schonburg; 14 miles N.N.W. of Waldenburg.

WEICHSELBURG, or *Weixelburg*, a town of the duchy of Carniola; 28 miles W. of Landtrafs. N. lat. 46° 5'. E. long. 14° 15'.

WEICHSELMUNDE, a fort built to defend the city of Dantzic, on the Vistula. In 1734 it was taken by the Russians; 4 miles N. of Dantzic.

WEICHTERSBACH, or WECHTERBACH, a town of Germany, in the county of Ifenburg, on the Kinzig; 23 miles E. of Francfort on the Maine.

WEICKERSBERG, or WEIKERSPERG, a town of Austria; 5 miles W. of Efferding.

WEICKERSHEIM, a town of Germany, in the principality of Hohenlohe, on the Tauber; 23 miles N.N.E. of Ohringen. N. lat. 49° 30'. E. long. 9° 58'.

WEIDA, a river of Silesia, which rises on the confines of Poland, and joins the Oder, near Breslau.

WEIDELBACH, a town of the principality of Anspach; 5 miles S.W. of Feuchtwang.

WEIDEMBERG, a town of Germany, in the principality of Culmbach; 7 miles E.S.E. of Bayreuth.

WEIDEN, a town of Bavaria, in the principality of Sulzbach, on the Nab; 17 miles N.E. of Sulzbach. N. lat. 49° 40'. E. long. 12° 3'.—Also, a town of the bishopric of Bamberg; 4 miles E. of Weismain.

WEIDENBACH, a town of Germany, in the margrave of Anspach; 5 miles S.S.E. of Anspach.

WEIDENBERG, a town of Germany, in the principality of Culmbach; 7 miles E.S.E. of Bayreuth. N. lat. 49° 55'. E. long. 11° 46'.

WEIDERAU, a town of Saxony, in the lordship of Schonburg; 4 miles N.E. of Penig.

WEIERN, a town of Bavaria; 23 miles S.S.E. of Munich.

WEIF. See WAIF.

WEIGEL, ERHARD, in *Biography*, a German mathematician, was born at Weida, in Nordgau, in 1625, and educated at Wensiedel, whither his parents were obliged to remove, on account of persecution, when he was three years old; and afterwards at the Gymnasium of Halle, where he enjoyed the advantage of being instructed in mathematics by

Bartholomew Schimpfer, a celebrated astronomer. The circumstances of his parents obliging him to return to Wundfeld, he there pursued his studies under an able tutor. Afterwards, encouraged by Schimpfer, he settled at Halle, where his reputation drew to him many pupils, by whom he was enabled to remove to Leipzig for farther improvement; so that in 1653 he was invited to be professor of mathematics at Jena. By favour of William, duke of Saxony, he was appointed mathematician to the court, and chief director of buildings; and thus the latter years of his life were chiefly employed in travelling. In the progress of his years he made many improvements in globes, and other instruments for facilitating the study of astronomy. This ingenious mathematician died in 1699. For a list of his works, which were many, we refer to his article in Gen. Biog.

WEIGELIA, in *Botany*, a Japanese genus, dedicated by Thunberg to the honour of Dr. Christian Ehrenfried Weigel, professor of Chemistry in the university of Gripfswald, in Upper Saxony, who published at Berlin, in 1769, when he was only 21 years of age, a *Flora Pomerano-Rugica*; but whose fame, as a deep and learned practical botanist, chiefly rests on his *Observationes Botanicae*, published as an inaugural dissertation, under his presidency, in 1772, in quarto, with three plates. This work, from its rarity, is not so well known as it deserves to be. The author corresponded with Linnæus, and communicated specimens of his new or doubtful plants.—Thunb. Jap. 6. Nov. Gen. 5. Schreb. Gen. 113. Willd. Sp. Pl. v. 1. 836. Mart. Mill. Dict. v. 4. Juss. 421. Lamarek Illustr. t. 105.—Class and order, *Pentandria Monogynia*. Nat. Ord. uncertain. Jussieu suspects it may belong to his *Apocinea*, the *Contortæ* of Linnæus; an opinion which the insertion of the style at the base of the germen seems to favour; but the serrated leaves are a great, perhaps insuperable, objection. If we might suspect an error as to the situation of the germen, the genus would readily range itself among Jussieu's *Caprifolia*; but the second species has more the character of his *Bignonia*, and renders it probable that Thunberg is merely mistaken in his idea of the simple nature of the germen.

Gen. Ch. Cal. Perianth superior, of five awl-shaped, erect, equal leaves. Cor. of one petal, funnel-shaped; tube the length of the calyx, internally hairy: limb bell-shaped, cloven half way down into five ovate, obtuse, slightly spreading segments. Stam. Filaments five, inserted into the tube, thread-shaped, erect, nearly as long as the corolla; anthers erect, linear, obtuse, cloven at the base. Pist. Germen superior, quadrangular, abrupt, smooth; style from the base of the germen, thread-shaped, rather longer than the corolla; stigma peltate, flat. Fruit unknown. Thunberg suspected there was a solitary naked seed.

Ess. Ch. Corolla funnel-shaped. Style from the base of the germen. Stigma peltate. Calyx superior, of five leaves.

1. *W. japonica*. Sessile-leaved Weigelia. Willd. n. 1. Thunb. Jap. 90. t. 16. Tr. of Linn. Soc. v. 2. 331. (Nippon Utsûgi; Kämpf. Am. Exot. 855.)—Leaves sessile, ovato-lanceolate.—Native of hilly situations in Japan, flowering in April and May. The stem is shrubby, with opposite, round, smooth branches, slightly quadrangular when young. Leaves opposite, sessile, pointed, copiously serrated, an inch, or rather more, in length, veiny, smooth on both sides, except the veins, which are hairy; paler beneath. Flower-stalks axillary, compressed, three-flowered, longer than the leaves, with two awl-shaped bractæas at the

base of each partial stalk, and two more about half way up. Flowers about an inch long, reddish-purple. Thunberg's description, in the *Flora Japonica*, confounds both species together, and is therefore here necessarily corrected.

2. *W. coraeensis*. Large-flowered Weigelia. Thunb. Tr. of Linn. Soc. v. 2. 331. Willd. n. 2. (Korei Utsûgi; Kämpf. Amoen. Exot. 855. Ic. Select. t. 45.)—Leaves stalked, obovate.—Native of Corea, from whence Kämpfer supposes it was brought to Japan. He describes it as *shrub* with beautiful flowers, smelling like cloves, and changeable in colour, being snow-white, flesh-coloured, and red, on the same plant. His excellent drawing, among those engraved and distributed through the munificence of Sir Joseph Banks, throws more light upon this species, and indeed upon its genus, than any thing else we have met with. It appears to be a climbing or trailing *shrub*, with round branches, and opposite stalked leaves, very like those of the *Hydrangea hortensis* in size and figure, being thrice the length of the first species, and obovate with a point. Flower-stalks axillary and terminal, three-flowered, an inch and a half long, with awl-shaped bractæas. Tube of the corolla slender, above half an inch long, twice the length of the calyx; limb bell-shaped, twice the length of its tube, divided half way down into five broad, obtuse, horizontally spreading segments. Stamens projecting beyond the mouth. Anthers incumbent. Stigma large, peltate, flat. Nothing appears respecting the germen, or its situation. We do not clearly understand the second of Kämpfer's separate figures, which is perhaps an under view of the corolla.

WEIGELSDORF, in *Geography*, a town of Bohemia, in the circle of Koniggratz; 2 miles W. of Trautenaue.

WEIGELSHAUSEN, a town of the duchy of Wurzburg; 5 miles W.S.W. of Schweinfurt.

WEIGENHEIM, a town of Germany, in the lordship of Schwarzenburg; 10 miles S.S.W. of Schainfeld.

WEIGERSTORFF, a town of Austria; 6 miles S. of Wells.

WEIGH, WAY, or WEY, *Waga*, a weight of cheese, wool, &c. containing two hundred and fifty-six pounds avoirdupois. Of corn, the weigh contains forty bushels; of barley or malt, six quarters.

In some places, as Essex, the weigh of cheese is three hundred pounds. See MEASURE.

“Et decimam caesi sui de Herting, præter unam peisam, quæ pertinet ad ecclesiam de A. Mon. Angl.” where *peisa* seems to be used for a weigh.

Coke also speaks of weighs of bay-salt.

WEIGH-Beams are steel-yards for the weighing of goods upon wharfs, &c.

WEIGHER, an officer in divers cities, appointed to weigh the commodities bought and sold, in a public balance, &c. These weighers are generally obliged by oath to do justice to both parties; and to keep a register of the things they weigh.

In Amsterdam there are twelve weighers, established into a kind of office. As it was formerly allowed them to touch the strings of the balance in weighing, it was easy for them to favour either the buyer or seller, according as the one gave them more money than the other. To prevent which abuse, it was charged on them, by an ordinance of the burgomasters in 1719, not to touch the balance in any manner whatever.

WEIGHGATT, in *Geography*, a name given to the fruit called WAYGATT, (which see,) from the wind which blows through this fruit (*waikan*, to blow,) because a strong S.W. wind blows out of it. It is also called Hindelopen. See Martens's Voyage, p. 27.

WEIGHING,

WEIGHING, the act of examining a body in the balance, to find its weight.

The distillers in London weigh their vessels when full; and for a half hoghead, which is thirty-one gallons and a half, allow two hundred one quarter and eleven pounds for the cask and liquor. For a puncheon, they allow six hundred one quarter and two pounds; for a Canary pipe, eight hundred a half and seventeen pounds.

WEIGHING-Cage, in *Agriculture*, a sort of machine or contrivance which is made in somewhat the form or manner of an open box or cage, by means of which any small animal, such as a pig, sheep, calf, or any other of a similar kind, may be very easily and expeditiously weighed, and with sufficient accuracy and correctness for the purposes of the farmer, store-master, and grazier. It is constructed on the principle of the common steel-yard. It has a strong wooden frame, on which there are steel centres, in which the pivots of the lever are hung. Upon the short side of the lever is suspended a sort of coop, surrounded by strong net-work, in which the animal intended to be weighed is put and secured; the point of suspension is connected with the coop by means of two curved iron-rods, which at the same time form the head of it. A common scale, in which the weights are to be put, is hung on the longer side of the lever. See **STEEL-Yard**.

WEIGHING-Chair, a machine contrived by Sanctorius, to determine the quantity of matter carried off from the body, and that of food taken at a meal; and to warn the feeder when he had eat his quantum.

That ingenious author, having observed, with many others, that a great part of our disorders arises from the excess in the quantity of our foods, more than in the quality thereof; as also how much a fixed portion, once well adjusted, would, if kept to regularly, contribute to health; bethought himself of an expedient to that purpose. The result was the weighing-chair: which was a chair fixed at one arm of a sort of balance, wherein a person being seated at meat, as soon as he had ate his allowance, the increase of weight made his seat preponderate: so that, descending to the ground, he left his table, victuals, and all, out of reach.

WEIGHING-House, a building furnished with a dock, and conveniences for gauging or ascertaining the tonnage of boats that are to be used on a canal.

WEIGHING-Machine for Turnpike Roads, in *Mechanics*, a machine for weighing heavy bodies, and particularly wheel-carriages. This is commonly done in order to ascertain if a carriage is within the weight allowed by law to be carried by such carriage on the turnpike-roads; a weighing-machine, or weigh-bridge, being fixed at every turnpike-gate. See **TURNPIKE**.

Formerly immense machines were used for this purpose: the machine was erected in an open building, beneath which the road passed, so that a cart, waggon, or other carriage, could be drawn under it; strong chains were then passed beneath the body of the carriage, to attach it to the extremity of an immense steel-yard. The fulcrum of the steel-yard was suspended by a lever, or by pulleys and crane-work, from the top of the building; and when the carriage was properly secured, the steel-yard was hoisted up by the crane-work, so as to suspend the waggon, and it could then be weighed by applying the sliding-weight of the steel-yard to different parts of the divided bar. Several curious machines of this kind are described by Leopold, in his *Theatrum Staticum*, 1724.

This method was tedious and dangerous; but when turnpike-roads became more common, a very superior machine was introduced, and we now find one at almost every

turnpike-gate. It is called a weigh-bridge, because the carriage is drawn upon a wooden platform or bridge, which is placed over a pit, made in the line of the road, to contain the machinery. The pit is walled within side, and the platform is exactly fitted to the walls of the pit; but as it does not touch the walls, it is at liberty to move freely up and down. The platform is supported by levers, placed beneath it, and is exactly level with the surface of the road, so that the carriage is easily drawn on to it. This is done without any difficulty or loss of time, because the platform is in the direct line of the road, and the carriage is only required to stop for a minute whilst its wheels stand fairly upon the platform, and the horses stand upon the solid ground beyond the platform. A few small weights put into a scale, like that of a common balance, determine the weight of the carriage and its load. If the weight of the carriage is previously known, the weight of the load may be found, by deducting the weight of the carriage from the total.

This weigh-bridge is placed at the side of a small house, which usually serves as a lodgement for the gate-keeper, and the scale is situated within the house. The platform is supported by two double levers contained in the pit; the ends of these levers are borne up by a long horizontal lever, which passes through one of the side-walls of the pit, and enters into the house: from the end of this lever, a small iron rod is carried up to one end of a common scale-beam or balance, from the other end of which the scale is suspended. All the levers are of the nature of steel-yards, that is, the weight or load of the bridge is applied upon the levers which support it, at points very near to their respective fulcrums, or centres of motion; whilst the ends of these levers are supported, at a very considerable distance from their fulcrums, by the long lever, and they bear upon this lever at a point very near to its fulcrum; but the counterbalancing force, that is, the effort of the weights in the scale, is applied to the extreme end of the long lever, very far distant from the fulcrum. For this reason, a small weight, as one pound for instance, placed in the scale, will bear up a large weight, for instance, 60 pounds, or one hundred weight placed upon the platform, according as the machine is constructed. This has an advantage, besides the convenience of small weights, *viz.* that the platform with the carriage does not sink down any perceptible quantity during the action of weighing; for when the weight in the scale is brought to equilibrium with the load, any motion or space which the small weight passes through, when the scale-beam vibrates, must be to the space which the platform and carriage pass through at the same instant, in the ratio of the load to the weight. Sometimes, instead of using a scale-board and detached weights, a long steel-yard is employed, with a weight to slide along upon it to different distances from the centre, until it will counterbalance the load on the platform; in that case, the lever is graduated to shew the weight upon the platform.

Salmon's Patent Weighing Machine.—This is very generally used in the vicinity of London; it points out the weight on a dial.

Plate II., Engines, contains figures of a weighing machine of the best kind. *Fig. 1.* is a horizontal plan of the levers contained in the pit, the platform being taken off to expose them. The under side of the platform is shewn at *fig. 2.* and *fig. 3.* is a vertical section of the whole machine.

E E (*fig. 3.*) is the platform; its upper surface is exactly level with the ground, and the edge of the planking of the platform is fitted into a border or frame which surmounts the side walls of the pit, leaving a small crevice all round its edges, so that the platform does not touch the fixed frame,

WEIGHING-MACHINE.

although it is very near to it. The platform is composed of a strong frame of wood (as shewn in *fig. 2.*), and the upper side is covered with wood planking. It is likewise defended from wear, by iron-bars and large-headed nails, which are fastened on the upper side. Near each of the four angles of the platform a piece of iron is fixed, as shewn by *b*; and it is on these four points that the platform is borne. When the platform is put in its place, these pieces of iron apply to the pins *bb* (*fig. 1.*), which are fixed in four strong iron levers, marked *A A*, *B B*. Each of these levers is supported at the extreme end *c*, on a fulcrum or centre-pin resting on a metal support, as shewn in *fig. 4*, which is borne by a piece of timber *oo*, worked into the walls of the pit at the angle. At the opposite ends the levers *A A* are brought together, and *B B* the same, so that all four meet in two points *aa*, and by means of links, shewn in *fig. 5*, are all connected with a long lever *CC*. This rests on a support or fulcrum *D*, borne by a pillar erected from the bottom of the pit. The end of the lever at *I* is received between two uprights to guide it, but do not any way confine its motion. In the common machine, it is from the extreme end of the lever *C D* that the iron rod before mentioned is carried up to the scale-beam, or steel-yard, as before described; but the patent machine in the figure is differently constructed in that part.

The fixed centres *c*, of the levers *A A* and *B B*, are at the ends of those levers, and the points *bb*, on which the platform bears, are very near to the centre *c*; but the distance of the points *a* from *c* is nine times as great as from *c* to *b*, consequently a force of one pound applied to lift up the levers at the point *a* would balance nine pounds laid upon the platform. In like manner the distance from the point *a* to the fulcrum *D* is only one-seventh part of the distance from the fulcrum to the end of the lever *C*; hence, one pound applied to lift up the end of the lever *C* would raise seven pounds applied at the point *a*, and seven pounds applied at *a* would balance sixty-three pounds placed on the platform. To weigh with a machine of this kind, if we use a scale and balance connected with the end of the long lever, we must use weights which are only one sixty-third part of the marks which they bear.

Mr. Salmon's machine operates in a much more perfect manner, by the help of a self-adjusting balance-wheel, which will weigh every different body, without employing any loose weights; and it shews the weight by means of an index and dial, like that of a clock. To effect this, another lever or steel-yard *FG* is applied, whereof *F* is the fulcrum, and *f* the point from which a link *C* descends to the end of the long lever *C D*. At the extreme end *G*, a strap is attached to ascend to the balance-wheel *ii*.

Now, as the distance *Ff* is only one-tenth of the distance *FG*, one pound applied to lift up the end *G* would raise ten pounds at *f*, or $10 \times 63 = 630$ pounds placed on the platform.

To draw the end *G* of the lever upwards, a thin leather strap *g* is attached to it, and the upper end of this is coiled round a small roller *b*, which is fixed upon an horizontal axis, as is shewn on a larger scale in *fig. 7*, where the axis is marked *bb*. This is reduced to small pivots at the extremities, which are borne by friction-wheels *aa*, to render its motion as free as possible. On the same axis *b* is fixed a wheel *ii*, (see also *fig. 6.*), and against the arms of this wheel a spiral ledge is fixed, with a sufficient projection to admit a fine silk line to wind upon the spiral, when the wheel is turned round. A weight *k*, which is suspended to the line, forms the counterbalance to the load placed upon the weigh-bridge (see *fig. 3.*), and the weight of the load is determined

by the distance which the roller and wheel *i* are turned round. This distance is shewn by an index *c* fixed on the extreme end of the axis *b*, and pointing to different divisions engraved round a dial, as shewn in *fig. 6*.

This single weight *k* can counterbalance all the different weights which may be placed on the platform, because the line by which the weight *k* is suspended, when it winds upon the circumference of the spiral, continually applies itself at a different distance from the centre of the axis, so as to operate with greater force. Hence, when any weight is placed upon the platform *E*, it presses down the levers *A A* and *B B*; these depress the long lever *C D*, and this again actuates the lever *F G*, and draws down the strap *g*, which unwinds from the roller on the axis *bb*, so as to turn it round, together with the wheel and spiral. The weight *k* winds upon the spiral, but the suspending line soon arrives at that part of the spiral where its radius is sufficiently increased, to enable the weight *k* to counterbalance the load upon the platform; the balance-wheel being then come to an equilibrium, will move no farther, and the index points out upon the dial the weight of the load upon the platform.

The spiral originates in the central part, at a circle which is of the same diameter as the roller, upon which the strap *g*, *fig. 3.* winds; and the weight *k* must be equal to the six-hundred-and-thirtieth part of the weight of the platform and levers *A A*, *B B*, when there is no weight upon it. When the weight *k* hangs from this commencement of the spiral, the index *c* stands at zero, as shewn in *fig. 6*. The spiral is so made, that to turn it round sixty degrees will require one ton weight to be laid on the platform, and every additional ton will turn the wheel and index round another sixty degrees, so that the machine will bear six tons before the index makes a complete revolution. Each space of sixty degrees is divided into twenty parts, which represent hundred weights; and each one is subdivided into halves or quarters, which divisions are very apparent on a large dial.

In constructing a machine of this kind, every attention must be paid to accuracy in the centres of motion of the different levers; all these points should be made of steel, and hardened. The form of the centres should be that of a sharp edge, like a blunt knife, with the edge resting on a surface of hard steel, made rather concave, (see *fig. 4.*) Centres, or bearing points of this kind, made sharp, will move with very little friction; and if the steel is good, and perfectly hard, the edges will not become blunt in many years' use. In all cases, the bearing-pins with the sharp edges must be fixed in the levers; because if the levers were made with plain surfaces, and to have sharp pins to bear upon them, there would be no certainty as to the effective lengths of the different levers, and they would vary in their power whenever the sharp edge changed its place upon the supporting surface.

The four principal levers, *A A*, *B B*, are made double, or with open loops at the ends, as shewn in *figs. 1* and *4*; two steel pins are put through the double part, one of them marked *c*, being made with a sharp edge at the lower side, but the other, *b*, is sharpened on the upper side. The former bears upon a fixed support faced with hard steel, and the other receives the metal stems, *b*, *fig. 2.* which are fixed to the under side of the platform. The two levers, *A A*, are joined together at the point *a*; and the two levers, *B B*, are also joined in a similar manner. Each pair of levers are connected by a cross-bar, as shewn in *fig. 1*, so as to make two triangles.

The ends *p* or *s*, *fig. 5.* of the compound levers *A A* or *B B*, where they join together, have a screw fitted through them, as shewn in *fig. 5*; the ends of these screws are made

WEIGHING-MACHINE.

of steel, and sharp-pointed, in order to rest in a cup or socket, *r*, of steel, formed in the lower part of a loop or link *L*. The upper end of the loop is suspended upon a sharp-edged pin fixed in the lever *C D*, *fig. 1*, which levers are marked *K* and *H* in *fig. 5*. The link belonging to the lever *A A* is suspended on one end of this pin, and the other loop upon the other end of the same pin. The lever *G* is made just the same as a common steel-yard.

The spiral, *fig. 6*, must be made very correctly in brass, and the line which winds upon it should be very flexible, and of equal thickness. After every care has been taken to make all parts of the machine very accurately, they must be put together; and known weights being laid upon the platform, the divisions on the dial should be laid down from the positions of the index. If the dial is thus divided by actual experiment, the machine will weigh very accurately; but its sensibility will depend upon the sharpness of the centres of the levers, and the hardness of the steel. When it is in good order, the addition of a quarter of a hundred weight to three or four tons, on the weigh-bridge, ought to produce a motion of the index. In an average state of the machine, it may be depended upon to within half a hundred weight.

Mr. Salmon had a patent for this machine in 1796, but his invention is confined to the balance-wheel and spiral, as shown in *figs. 6* and *7*. These parts, separated from the great machine, make a very accurate and complete weighing machine by themselves, when inclosed in a box; a common scale, to contain the goods which are to be weighed, being suspended from the lower end of the strap which winds round the roller.

The introduction of these index weighing-machines for turnpike-roads is of great utility, to diminish those incessant disputes between the gate-keeper and the carriers respecting the weight of their loads. In the common weighing-machines, the weights, being loose and of an arbitrary weight, may be changed or diminished by the gate-keeper to make the loads appear greater; and the carrier has no means of detecting this fraud, except by unloading and weighing his cargo in small quantities, which is scarcely practicable; neither can he be assured of the manner of weighing, even if the weights are just. Another source of uncertainty is, whether the machine be in exact balance when there is no load on the platform; for as the wood imbibes wet and becomes dirty, it makes considerable variations in the balance of the machine. To put the machine in equilibrio, a heavy weight is hung on the end of the lever *C D*, *fig. 3*, and can be placed nearer to or farther from the centre. This should always be adjusted, but is frequently neglected, and is difficult of detection.

With the index-machine all these difficulties are avoided: it is constructed by a maker whose character is at stake, and when once truly made will continue in the same state, if the whole is locked up, so that the gate-keeper cannot have access to the index. The only defect arising from age and wear is, that the index becomes less sensible, and moves slightly and by starts. This the carrier can try at any time by pressing his foot upon the platform; and he can always tell if the index returns to zero when the load is removed; and if it does not, he can see how much the machine is out of balance.

The law respecting weighing carriages is an inducement to fraud in the gate-keepers; a certain weight is allowed by act of parliament to be carried by each description of carriage, which weight is regulated according to the width of the carriage-wheels, the number of horses, and the season of the year, whether winter or summer.

If the load does not exceed the allowed weight, a certain toll is charged for the carriage; but for all excesses of weight, a very heavy toll is charged on each hundred-weight as a penalty, the amount of which is increased in proportion to the quantity of over-weight. (See TURNPIKE.) It is a valuable prize for a gate-keeper to find a carriage overloaded.

WEIGHING-Machines for small Weights. These are of different constructions, according to the use for which they are intended.

In some the weight of any body is determined by putting loose weights into an opposite scale, and these weights may be either equal weights to those which they are to denote, as in the case of a balance with equal arms, or the weights may be smaller and applied to the longer arm of an unequal balance, as in the steel-yard. The former is by far the most accurate, and from the facility of proving its accuracy by placing the weights in either of the scales, it has become the legal mode of weighing. Steel-yards are accurate if carefully used, but afford many opportunities of fraud in the hands of dishonest persons.

Mr. Medhurst's patent weighing-machine is very useful in shops and warehouses, being more convenient than the common balance and scales, and having the same property of equal arms to the lever. The scale-boards, instead of being suspended from the arms of the balance, are securely poised between the arms of a double balance-beam, and are placed at such a height as is most convenient to receive the goods which are to be weighed. The weights are to be put into the opposite scale, but can be put in either; and the load on the opposite one, if there is any doubt of the accuracy of the balance.

When more considerable weights are to be weighed, equal weights are so inconvenient, that small machines, such as are used for carriages, are to be preferred for convenience, as they require only small weights in the scale.

There is another kind of weighing-machines which requires no loose weights, but shews the weight by a pointer or index upon a divided arch, or on a dial-plate.

The index and balance-wheel of Mr. Salmon's machine, when detached, make a very complete weighing instrument of this kind, as before described.

Other index machines act with a pendulum: thus, the scale to receive the goods is suspended from a lever, to which a pendulous arm is attached with a heavy weight at the extremity to form a pendulum. The application of any weight in the scale tends to remove the pendulum from its vertical position; and it is a property of a pendulum to increase in its effort to return to the perpendicular, in proportion to the distance which it is removed from it. The quantity of deviation from the perpendicular is indicated by an index or pointer to the divisions on an arch, and these divisions are numbered to denote the weight. The machine used for weighing hanks of cotton is of this kind, and apothecaries sometimes use a similar instrument.

Many of the index machines are made with springs, which are bent by the application of the weight; and the degree of their flexure, as determined by some indexes, is an indication of the weight applied. Several machines of this kind are described in our article DYNAMOMETER; and although they are rather differently constructed, to fit them for measuring the strength of horses, &c. all of them may be converted to weighing-machines, by applying a proper suspending hook, with a scale to receive the matter to be weighed.

A curious machine of this kind was made many years ago by M. Hanin of Paris, and presented to the Society of Arts. The weight is determined by the degree to which a femi-

a semicircular steel spring will be bent, when the weight is applied to force the ends of the spring to recede from each other. The quantity is shewn by an index, which turns round over a circular dial-plate, like a clock-hand. The principal curiosity of this machine is, that the dial contains thirteen concentric circles, each divided to shew the weight in the denominations of different countries; *viz.* on the two external circles are divisions to shew troy and avoirdupois weight in pounds; within this is a circle to shew the corresponding number of Paris livres; next Portuguese arrobas, and Spanish arrobas; then Dutch, Swedish, Danish, and German pounds; so that the instrument becomes an universal table for the ratios of these different weights.

WEIGHING-Machine, in *Agriculture and Rural Economy*, a sort of machine or contrivance made use of for the purpose of weighing neat cattle and some other kinds of animals alive, as well as different other uses. It is a machine which is perfectly simple and easy in its manner of construction. It has a beam of the steel-yard kind, at the top of which is a pin, on which the suspension of the beam is made. There is a counterpoise which is moveable along the beam by means of a sliding socket, on which is raised an iron arm, supporting a wooden box or scale to receive the counterbalancing weights in the operation of weighing. There are different levers, which are hung on a projecting pin of the beam by one end, the other resting on an iron support. There is a lid or platform, on which is placed the subject to be weighed; to the under side of this, at each corner, are attached blocks, from which proceed iron pieces, similar in form to the supporting piece, but reversed in position: by means of these four pieces the lid or platform stands with its whole weight entirely on the lever; other pieces applying themselves to the levers at a small distance nearer to the centre of the machine than to the supporting piece.

In the operation of weighing, the subject to be weighed being placed on the lid or platform, pressed by the different pieces on the levers, which by their suspension on the beam determine it from its even position by a quantity proportioned to the weight of the subject, which is expressed by the counterbalancing weights required to be placed in the box or scale. See **STEEL-YARD**.

A machine of this nature is of vast utility and importance in the different systems of grazing, feeding, and fattening various sorts of live-stock and domestic animals, especially where they are carried on to any considerable extent, not only in ascertaining and marking the progress which is made by the different animals, and in shewing how they pay for the use of any particular kind of food, or what power and property it may have in promoting the fattening process, but in many other ways.

Weighing-machines, constructed upon the same plan as those used on the public roads, are applicable, too, in the above cases, and many others of the rural kind, being ready and convenient for such uses.

WEIGHING of the Air. See **WEIGHT of Air**.

WEIGHING Anchor, in *Sea Language*. See **ANCHOR**.

WEIGHT, in *Physics*, a quality in bodies by which they tend towards the centre of the earth, or in a line perpendicular to its surface. Or, weight may be defined, more generally, a property inherent in all bodies, by which they tend to some common point, called the centre of gravity; and that with a velocity in proportion as they are more or less dense, or as the medium through which they pass is more or less rare.

Weight and gravity are generally considered as one and the same thing. Some philosophers, however, distinguish gravity as the quality inherent in the body, and weight as

the same quality exerting itself according to its natural tendency. See **GRAVITY**, **GRAVITATION**, and **DENSITY**.

Sir Isaac Newton demonstrates, 1st, That the weights of all bodies at equal distances from the centre of the earth, are directly proportional to the quantity of matter that each contains: whence it follows, that the weights of bodies have no dependence on their shapes or textures; and that all spaces are not equally full of matter.

2^{dly}, On different parts of the earth's surface, the weight of the same body is different, owing to the spheroidal figure of the earth, which causes the body on the surface to be nearer the centre in going from the equator toward the poles; and the increase in the weight is nearly in proportion to the versed sine of double the latitude; or, which is the same thing, to the square of the right sine of the latitude; the weight at the equator to that at the pole being as 229 to 230; or, the whole increase of weight from the equator to the pole, is the 229th part of the former.

3^{dly}, That the weights of the same body at different distances above the earth, are inversely as the squares of the distances from the centre, so that a body at the distance of the moon, which is sixty semi-diameters from the earth's centre, would weigh only the 3600th part of what it weighs at the earth's surface.

4^{thly}, That at different distances within the earth or below the surface, the weights of the same body are directly as the distances from the earth's centre: so that, at half way toward the centre, a body would weigh but half as much, and at the very centre it would have no weight at all.

5^{thly}, A body immersed in a fluid, which is specifically lighter than itself, loses so much of its weight, as is equal to the weight of a quantity of the fluid of the same bulk with itself. Hence, a body loses more of its weight in a heavier fluid than in a lighter one, and therefore it weighs more in a lighter fluid than in a heavier one.

The foregoing principles laid down by Newton are universally admitted as correct, with the exception of the proportional weight of bodies on different parts of the earth's surface; for it is important to observe, that he founded his calculation of the earth's ellipticity on the hypothesis of its being homogeneous, which is not the case; and hence he makes the equatorial diameter greater than the polar axis, as 230 to 229. But from the numerous experiments since made on the pendulum in different parts of the world, the ellipticity is found to be not so great.

By the investigations on this subject by the marquis de Laplace, (*Mecanique Celeste*, vol. ii.) the ellipticity is found to be $\frac{1}{230}$; and the calculations and experiments of other astronomers concur nearly in this result, making it on an average about $\frac{1}{230}$. In our article **STANDARD**, we have given tables of those determinations, and likewise of the principal experiments made on the pendulum in different latitudes; and we shall here add some further investigations and new calculations, as essentially connected with our subject **WEIGHT**, and of peculiar interest at the present time.

The chevalier Delambre, in his "Astronomie," vol. iii. p. 585, gives the following simple and elegant exposition of the pendulum, with other useful formulæ for finding the earth's ellipticity, &c.

Let h be the height of the place of observation above the level of the sea; R , the radius of the earth; then the length of the pendulum is to be multiplied by

$$\left(\frac{R+h}{R}\right)^2 = \left(1 + \frac{2Rb + b^2}{R^2}\right) = 1 + \frac{2b}{R}.$$

WEIGHT.

Let L be the length of the pendulum at the equator; for another latitude, it will be $L + a \sin.^2 H$, so that a is the excess of the polar pendulum above the equatorial pendulum, H being the latitude of the place.

Let m and n be the two pendulums observed in two very different latitudes.

$$\begin{aligned} m &= L + a \sin.^2 H, \\ n &= L + a \sin.^2 H', \end{aligned}$$

$$m - n = a (\sin.^2 H - \sin.^2 H') = a \sin. (H - H') \sin.$$

$$(H + H') : \text{hence } a = \frac{m - n}{\sin. (H - H') \sin. (H + H')}$$

If there be a greater number of similar equations, put in each the numerical value of $\sin.^2 H$, and determine the two constant quantities, L and a , by the sum of the observations, employing, if you think proper, the method of the smaller squares.

Now the ellipticity is proved to be $0.00865 - \frac{a}{L}$. We

have then a value of the ellipticity, which may be compared with that of the degrees. It was in this manner that M.

Mathieu found the ellipticity to be $\frac{1}{298.2}$, by the six ac-

tual measurements of the pendulum made on the meridian from Dunkirk to Formentera. So far Delambre.

From the above equations and formulæ it is manifest, that if L , the length of the equatorial pendulum, and a , the difference between it and the polar pendulum, be known, all other questions connected with the subject may be accurately determined; and hence it is, that the important problem of

measuring the pendulum has long engaged, and still continues to command the attention of the first astronomers in Europe.

Laplace, in the *Mecanique Celeste*, gives the following values of L and a ; viz. $0^m.990631631 + 0^m.005637 \sin.^2$ latitude, from which formula the lengths of the pendulum may be computed in all latitudes; but the same learned author has recently published another formula in the *Connoissance des Temps* (1820, page 442), which is thus given.

“Mathieu, by a new discussion of all the observations of the pendulum, in using the results of Borda’s experiments reduced to the level of the sea, finds the following expression of the length of the pendulum,

$$0^m.990787 + 0^m.0053982 \sin.^2 \text{ latitude.}$$

“In this expression I have diminished by the two-thousandth of a millimetre the result of Borda upon this length, for the correction of the radius of the cylinder, which formed the knife edge; a radius which I value at eight thousandths of a millimetre.

“The experiments now about to be made with particular care, in the two hemispheres, will shed new light on the coefficient of the square of the sine of the latitude, or on the variation of weight on the surface of the earth.”

From the above formula we have computed the following table, and have found the earth’s ellipticity to be $\frac{1}{298}$. By this also the increase of the weight of a body from the equator to the poles is $\frac{1}{298}$ of the whole, whereas that deduced from the *Mecanique Celeste* is $\frac{1}{278}$, which proportion has been adopted by Poisson, Biot, and other writers on the subject.

TABLE shewing the comparative Weight of Bodies on different Parts of the Earth’s Surface, with the proportional Length of the Seconds Pendulum, and also its daily Number of Vibrations in each Latitude: supposing it correct at the Greenwich Observatory, that is vibrating 86400 Seconds in 24 Hours.

WEIGHT.

In computing the foregoing table we have, as on former occasions in this work, reckoned the French metre at 39.371 English inches, and the correctness of this measure is of the greatest importance to science. It was that originally determined by M. Picquet, in the National Institute, by comparing the platina metre with the brass yard made by Mr. Troughton, which was agreed upon by the Royal Society of London, as the best medium among our different standards, and the most accurate in its divisions. In making the necessary deductions for the effects of temperature on the different metals, Borda's tables of expansion were used; but from other tables and standards different lengths of the metre have been determined; particularly by Dr. Maskelyne, who made it 39.370226, and lately by Capt. Kater, who comes still nearer to Picquet, making it 39.37071. But unless such measurements are made from the same standard yard, and with the same tables of expansion, perfect agreement cannot be expected; and then it will be necessary to determine the important question, whether such tables and standards are quite correct? In short, an approximation to perfect accuracy is as much as can be hoped for. It is, however, satisfactory to observe, that the difference between the determinations of M. Picquet and Capt. Kater is scarcely discernible, even in the most delicate operations of an observatory, as it does not amount, when applied in measuring the pendulum, to more than one-third of a second in twenty-four hours. But for all general purposes the difference is wholly imperceptible.

This near agreement, therefore, confirms the propriety of our continuing Picquet's measure, which is sanctioned by general usage both in England and France, and has the additional advantage of numerical simplicity, which, for commercial purposes, is no slight recommendation.

Before we enter upon the subject of commercial weight, some general view ought to be given of the operations now about to take place on the pendulum in the two hemispheres, as alluded to in our quotation from Laplace.

The experiments intended by the French, in a voyage of discovery to the southern hemisphere, are to be made with pendulums of an extremely simple construction, the astronomical rates of which are previously ascertained at the Paris observatory. In these pendulums no maintaining power is applied, nor any compensation for temperature. The thermometer, therefore, and the magnitude of the arc of vibration, must be continually observed, and the necessary corrections applied, as in the experiment of Borda explained in Delambre's *Astronomie*, vol. iii. p. 579. Pendulums of a similar construction were employed by the French astronomers, M. Biot and M. Arago, at the royal observatory of Greenwich, and in other parts of Great Britain during the last year (1817); but the result of their experiments has not yet reached us.

A very correct and beautiful apparatus has lately been erected at our royal observatory, for the purpose of measuring the length of the pendulum; and also with a view of determining, with extreme exactness, the difference of the force of gravity at Greenwich and Paris, or, in other words, the comparative weight of bodies in these two latitudes.

This apparatus does not very essentially differ from that of Borda, except that a cylindrical rod of a given length is assumed as a standard, and the difference between this cylinder and the whole vibrating system is determined by a micrometer motion given to the steel table. In the French

apparatus the steel table remains fixed, and the measuring-rod is lengthened by means of a screw, till the lower surface comes in contact with the plane of the table.

We have likewise observed, that in Mr. Pond's apparatus, the pendulum of the clock is, by an ingenious contrivance, brought almost into contact with the experimental pendulum, by which the coincidences can be distinctly observed with a high optical power.

In the expedition which has been lately sent by the British government to explore the arctic regions, experiments are to be made for similar purposes, but with different apparatus. Two famous clocks, by Shelton, which were used by captain Cook, are sent. Each is furnished with a new brass pendulum of an entire piece, which can only vary in length by change of temperature, and this is to be allowed for from constant observation of the thermometer. The rates of the clocks in London have been accurately determined; and if the same can be ascertained at or near the pole, the result will be very important.

In concluding our view of the philosophy of weight, its varieties on the surfaces of the planets should be noticed; which are determined on the same principles as on the surface of the earth. See *PLANET*, and *SYSTEM*.

The weight of bodies on the surface of the sun is computed by Laplace to be about twenty-five times greater than on that of the earth; without, however, allowing for the diminution of gravity by centrifugal force, which he calculates to be about $\frac{1}{3}$. See *CENTRIFUGAL Force*.

WEIGHT, in *Commerce*, denotes the quantity of any commodity or substance, which is determined by being placed in a scale against some known standard or weight. The art of weighing is therefore of the utmost importance, as it furnishes the best practical means of ascertaining the quantity of matter in any given body, and thence the value of most of the necessaries of life.

Weights are generally made of stone, iron, lead, brass, or mixed metal; and they are mostly stamped by proper authorities, denoting that they have been sized or compared with some known or legal standard. See *STANDARD*, and also *MEASURE*.

The weights of all nations differ from each other, and frequently in the same country a great diversity prevails. The common denomination is the pound, of which there are mostly two sorts, one for weighing the precious metals, and the other for common articles; such are the troy and avoirdupois weights in England. The former is generally divided into twelve ounces, and the latter into sixteen. But their division and multiples, as well as relative proportions, are extremely various. We shall consider them here under two distinct heads, *viz.* *Ancient Weights*, and *Modern Weights*.

Ancient Weights.—From the great importance of weights and measures, their adjustments must have been coeval with the first regulations of civil society; and hence their origin is too remote to be traced by any authentic history. The only ancient weights that are known with any degree of certainty are those of the Jews, Greeks, and Romans.

The ancient Jews, having no stamped coin, weighed all their gold and silver in the following simple manner, dividing their talent into 50 maneh, and their maneh into 60 shekels.

WEIGHT.

TABLE I.—Jewish Weights reduced to English Troy Weight (from Arbuthnot).

Shekel										lb.	oz.	pwt.	gr.
										0	0	9	2 $\frac{2}{7}$
60	Maneh									2	3	6	10 $\frac{2}{7}$
3000	50	Talent								113	10	1	10 $\frac{2}{7}$

Note.—In reckoning money, 50 shekels made a maneh; but in weight, 60 shekels.

The weight of the Roman denarius, ounce, and pound, is otherwise stated as follows :

By Arbuthnot, the Denarius, (7th part of the Ounce)	}	English Grains.	
the Ounce			62,4
the Pound			437,2
the Pound			5246,4
By Christiani, the Denarius, (8th part of the Ounce)	}		
the Ounce			51,9
the Ounce			415,1
the Pound			4981,2

See DENARIUS.

Modern Weights, or rather weights used in modern times, are in general very remote in their origin. We shall begin with British weights, and follow with those of France, making accurate comparisons between both; after which the divisions of the weights of the principal trading places in Europe, and other parts of the world, will be given; with tables of their relative proportions, extracted, by permission, from the Universal Cambist.

English Weights.—By the twenty-seventh chapter of *Magna Charta*, the weights are to be the same all over England; but for different commodities there are two sorts, viz. troy weight, and avoirdupois weight.

The origin from which they are both raised is the grain of wheat, gathered in the middle of the ear: 32 of these well dried make one penny-weight, 20 penny-weights 1 oz., and 12 oz. 1 lb. troy. Stat. 51 Hen. III. 31 Edw. I. 12 Hen. VII.

By the laws of assize, from the reign of William the Conqueror to the reign of Henry VII., the legal pound weight contained a pound of 12 ounces, raised from 32 grains of wheat; and the legal gallon measure invariably contained 8 of those pounds of wheat, 8 gallons made a bushel, and 8 bushels a quarter.

Henry VII. altered the old English weight, and introduced a pound, under the name of troy, which exceeded

the old Saxon pound by $\frac{1}{3}$ of an ounce: in proof of this it is alleged, that Henry VIII. when he abolished the old pound in the eighteenth of his reign, and established the troy, declares that the troy pound exceeded the old pound by $\frac{1}{3}$ of an ounce.

This troy pound now in use, consisting of 12 ounces, contains 5760 troy grains, and the ounce therefore contains 480 grains; consequently 360 grains, equal to $\frac{3}{8}$ of the ounce, deducted from 5760, leave 5400 troy grains, equal to the weight of the old Saxon pound which he abolished. It appears, therefore, that the old Saxon pound was $\frac{4}{7}$ of the present troy pound; and as the avoirdupois pound of 16 ounces contains 7000 troy grains, the old Saxon pound was $\frac{3}{7}$ of the present avoirdupois pound.

Although formerly 32 grains made a penny-weight, it has in later times been thought sufficient to divide the penny-weights into 24 equal parts called grains, being the least weights now in common use.

The first statute that directs the use of the avoirdupois weight is that of 24 Henry VIII., which plainly implies that it was no legal weight till that statute gave it a legal sanction; and the particular use to which the said weight is thus directed, is simply for weighing butcher's meat in the market. How or when it came into private use is not clearly known. Phil. Transf. vol. lxx. part i. art. 3.

TABLE V.—Of Troy Weight, as used by the Goldsmiths, &c.

Grains.		
24	Penny-weight.	
480	20	Ounce.
5760	240	12 Pound.

The grain troy is divided into 20 mites, the mite into 24 doits,

WEIGHT.

doits, the doit into 20 perioits, and the perioit into 24 blanks. These divisions are imaginary, but there are real weights of decimal divisions to the thousandth part of a grain.

TABLE VI.—Of Troy Weight, as used by the Apothecaries.

Grains.			
20	Scruple. ʒ		
60	3	Drachm. ʒ	
480	24	8	Ounce. ʒ
5760	288	96	12 Pound.

This weight is essentially the same as troy weight, but differently divided. It is chiefly used for medical prescriptions: but drugs are mostly bought and sold by avoirdupois weight.

TABLE VII.—Diamond Weight.

Diamonds and other precious stones are weighed by carats, the carat being divided into 4 grains, and the grain into 16 parts. The diamond carat weighs $3\frac{1}{2}$ grains troy: thus,

Diamond Weight.	Troy Weight.
16 Parts = 1 Grain	= $\frac{1}{16}$ Grain.
4 Grains = 1 Carat	= $3\frac{1}{2}$ Grains.

TABLE VIII.—Of Avoirdupois Weight.

Drachms.				
16	Ounce.			
256	16	Pound.		
7168	448	28	Quarter.	
28672	1792	112	4	Hundred.
573440	35840	2240	80	20 Ton.

The drachm is subdivided into three scruples, and each scruple into ten grains; the pound or 7680 grains avoirdupois = 7000 grains troy, and hence 1 grain troy = 1097 grains avoirdupois.

Hence also - 144 lb. avoirdupois = 175 lb. troy.
And - 192 oz. ditto - - 175 oz. do.

The stone is generally 14 lb. avoirdupois weight, but for butcher's meat or fish it is 8 lb. Hence the hundred equals 8 stone of 14 lb. or 14 stone of 8 lb.

A stone of glass is 5 lb. A seam of glass 24 stone, or 120 lb.

The fother of lead is generally $19\frac{1}{2}$ cwt.
at Newcastle, 21 cwt.
at Stockton, 22 cwt.

Hay and straw are sold by the load of 36 trusses.

The truss of hay weighs 56 lb. and of straw 36 lb. The truss of new hay is 60 lb. until the 1st of September.

A view of local varieties of English weights will follow the present article.

TABLE IX.—Wool Weight.

Wool, like other common articles, is weighed by the avoirdupois, but the divisions differ from the above table: thus,

7 Pounds	-	-	=	1 Clove
2 Cloves	-	-	-	1 Stone
2 Stone	-	-	-	1 Tod
$6\frac{1}{2}$ Tods	-	-	-	1 Wey
2 Weys	-	-	-	1 Sack
12 Sacks	-	-	-	1 Last.

The Weights of Ireland are the same as those of England; and they are used for corn instead of measures, which seems to be the most correct method of dealing.

Weights of Scotland.—By the act of union passed in 1707, the weights and measures of England were to be adopted in Scotland, but their introduction there is by no means general.

The English troy weight and apothecaries' weight, however, are used throughout Scotland, in the same manner as in England, with the exception that the Scotch jewellers divide the troy ounce into 16 drops, each drop being 30 troy grains; whereas the English divide it into 20 penny-weights, and a penny-weight into 24 grains, as before stated.

The English avoirdupois weight is used for the sale of leather, soap, sugar, tea, flour, candles, and other groceries; also for selling rosin, wax, pitch, wrought metals, some Baltic goods, and all goods brought from England.

Scotch troy weight, also called *Amsterdam* and *French Weight*, is used for weighing iron, hemp, flax, Baltic and Dutch goods, meal, butcher's meat, unwrought pewter and lead, and likewise for some more articles. The pound, 16 of which compose a stone, contains 7616 troy grains: it is consequently nearly 9 per cent. heavier than avoirdupois, or 100 lbs. are equal to 108½ lbs. avoirdupois.

Trone Weight.—This weight was abolished by act in 1618. Its name is still retained in selling butter, cheese, tallow, wool, lint, hemp, hay, and some other home commodities; but the trone stone and pound are generally denominated by avoirdupois pounds and ounces. The trone pound always contains the same number of ounces avoirdupois, as the stone contains pounds. The weight of the stone, however, is variable. It appears from a recent publication (Kelly's Metrology), that there are about thirty different systems of weights and measures in Scotland.

Weights of France.—In order fully to explain this important part of our article, three different weights must be noticed; viz. the ancient system, called the "Poids de Marc;" the "Metrical System," begun in 1795; and the "Systeme Usuel," sanctioned by an Imperial decree of 1812.

The old French weight (poids de marc), the pound or livre, contains 2 marcs, 16 ounces, 128 gros, 384 deniers, and 9216 grains, and equals 7556 grains troy. The new or metrical system, also called the decimal system, has been already explained under our article STANDARD. The following are its divisions, with its proportion to the poids de marc and English troy weight. The gramme is the element of all weights, and it is multiplied and divided by tens in the following terms:

The word <i>Deca</i> prefixed means	-	-	10 times.
<i>Hecto</i>	-	-	100 times.
<i>Kilo</i>	-	-	1000 times.
<i>Myria</i>	-	-	10000 times.

On the contrary, for divisors, the word *Deci* expresses the

10th part,	-	-	-
<i>Centi</i>	-	-	100th part, and
<i>Milli</i>	-	-	1000th part.

WEIGHT.

TABLE X.

	Poids de Marc.		Eng. Troy Weight.			
	livres. on.	gros. grs.	lb.	oz.	dwt.	grs.
Bar or Cubic Metre of Water.	2042	14 0 14	- 2681	3	6	2
Myriagramme	20	6 6 63.5	- 26	9	15	1.46
Kilogramme	- 2	0 5 35.15	- 2	8	3	12.146
Hectogramme	- -	3 2 10.715	- 3	4		8.414
Decagramme	- -	2 44.2715	- 6			10.441
Gramme	- -	18.82715	-			15.4441
Decigramme	- -	1.882715	-			1.54441
Centigramme	- -	0.1882715	-			0.15444

The gramme weighs 5.648 drachms avoirdupois, and the kilogramme 35.3 oz. or 2 lb. 3 oz. 4.8 drachms avoirdupois. The *Quintal Metrique*, therefore, weighs 1 cwt. 3 qrs. 24 lb. avoirdupois.

The pound of the *Système Usuel*, is the half kilogramme; but the divisions are binary, according to the ancient system.

Weights of Spain.—The Castilian mark is used for the precious metals. In weighing gold, it is divided into 50 castellanos, 400 tomines, or 4800 grains; but for silver, the same mark is divided into eight ounces, 64 ochavos, 128 adarmes, 384 tomines, or 4608 grains. The commercial weight is also Castilian. The pound is divided into 2 marks, 16 ounces, 128 drachms, or 9216 grains.—25 pounds = 1 arroba; 4 arrobas = 1 quintal.

Weights of Portugal.—Gold and silver are weighed by the mark of 8 ounces; the ounce being subdivided into 8 outavas, 24 escrupulos, or 576 grains. The commercial pound is divided into 2 marks or 16 ounces, the ounce into 8 outavas or 576 grains.—32 lb. = 1 arroba; 4 arrobas = 1 quintal.

Weights of Holland.—Gold and silver are weighed by the mark of 8 ounces. The ounce is divided into 20 engels or esterlins; the engel into 32 aas. Thus the mark weighs 5120 aas. The commercial pound is 40 aas heavier than the above pound troy. It is divided into 2 marks, 16 ounces, 32 loots, or 128 drachms.—8 lb. = 1 stone; 15 lb. = 1 lispond; 100 lb. = 1 centner; and 300 lb. = 1 shippond.

A new system of monies, weights, and measures, similar to the decimal system of France, has been lately decreed for Holland, Brabant, and Flanders, by the king of the Netherlands.

Weights of Germany.—The weight for gold and silver is not the same in all parts of Germany, but the Cologne mark is every where the standard weight for coins. It is divided into 8 ounces, 16 loths, 256 pfenings, 512 hellers, 4352 eschen, or 65536 richt-pfenings. The pound or pfund commercial weight is generally divided into 2 marks, 16 ounces, 32 loths, 128 quintins, 512 pfenings, 1024 hellers. The larger weights are the shippond, the centner or quintal, the lispond, and the stein; but they do not in all places contain the same number of pounds, and their divisions as well as relative proportions are extremely various throughout the empire.

Weights of Italy.—The weights of Italy are various both in their divisions and relative proportions. Thus, at Rome, the pound for weighing gold and silver is divided into 12 ounces, the ounce into 12 drachms, 24 denari or scrupoli, 48 oboli, 144 filique or 576 grani. At Naples, the pound or libra is divided into 12 ounces, the ounce into 30 trapesi, and

the trapeso into 20 acini. At Genoa, Florence, Leghorn, and Milan, it is divided into eight ounces, the ounce into 24 denari or 576 grani. At Venice, the marc is divided into 8 oncie, 32 quarti, 192 denari, 1152 carati, or 4608 grani. The commercial weight in most of the above places is the same for light goods as for gold and silver, and is called peso sottile; but a heavier weight is used for coarse commodities, and is called peso grosso. Their cantaro or quintal varies from 100 to 250 lb., and in some places the great cantaro is 1000 lb.

Weights of Denmark.—The pound for gold and silver contains 2 marks, 16 ounces, 32 lots, 128 quintins, or 512 ort or pfenings. The pound commercial weight is divided like that for the precious metals. The shippond contains 320 lbs. 20 lisponds, or 3½ centners.

Weights of Sweden.—The mark for the precious metals contains 4384 aas; but for commercial purposes there are four other weights, viz. the victualie-wigt, divided into 32 lods or 128 quintins; the bergs-wigt or miner's weight, the landstads-wigt, and the metal-wigt. The pound of each of the three latter is divided into 16 lods, or 64 quintals.

Weights of Russia.—The pound in Russia used for all commodities is divided into 32 loths, or 96 solotnicks.—40 lb. = 1 pood, and 10 poods = 1 berquet.

Weights of Asia.—The weights of Asia are far too numerous and various in their divisions for our limits; but it may be observed, that decimal divisions are more general there than in Europe.

Weights of Africa.—Upon the Barbary coast and in Egypt, the weights are similar to each other in their divisions, but very different in their relative proportions. The principal weight is the cantaro, divided into 100 rottoli, which is likewise used in Italy, Constantinople, and several places in the Levant.

Weights of America.—The weights and measures generally used in America, are those of the countries by which the different settlements were originally colonized. Thus the Spanish weights are retained in all parts of South America except Brazil, where those of Portugal are used. In the United States of North America, the English system of weights and measures is still continued, although several plans have been proposed for changing them.

Comparison of Weights.—The following Tables shew the relation between English and foreign weights. Also the proportion of the latter to each other, which is found by a single stating in the Rule of Three, as in the following examples:

Example 1.—How many marks of Berlin weight are equal to 560 kilogrammes of France?

Because 159.29 marks of Berlin = 100 lb. English Troy (*per* Table XI.), and 37.31 kilogrammes, by the same Table, = 100 lb. English Troy; it follows that 37.31 kilogrammes = 159.26 marks of Berlin; therefore, say,

$$\text{As } 37.31 \text{ kilog.} : 159.29 \text{ marks} :: 560 \text{ kilog.} : 2390.84 \text{ marks.}$$

Example 2.—How many pounds commercial weight of Amsterdam are equal to 276 pounds of Leghorn?

Here, by Table XII., 91.81 lb. of Amsterdam = 133.56 lb. of Leghorn, both being equal to 100 lb. Avoirdupois; therefore,

$$\text{As } 133.56 \text{ lb. of Leghorn} : 91.81 \text{ lb. of Amsterdam} :: 276 \text{ lb. of Leghorn} : 189.7 \text{ lb. of Amsterdam.}$$

WEIGHT.

TROY WEIGHT.

TABLE XI.—Containing a Comparison of the Troy, or Gold and Silver Weights of different Countries; and shewing the Number of Pounds, Marks, Ounces, &c. of each Place, that are equal to 100 Pounds English Troy; and also the Weight of a single Pound, Mark, Ounce, &c. in English Troy Grains.

Plan for the Revision of foreign Weights, &c.—The commercial world will learn with satisfaction that a plan has lately been commenced, under the auspices of the British government, for revising the tables of comparison between foreign weights and measures; as it is well known that many of the tables in use abound in contradictory statements; and even where they agree, they are frequently found to differ from mercantile experience.

The origin of those tables of comparison cannot be traced. It is probable that they have been gradually formed through a long course of ages, from the casual reports of individuals in different countries. When, therefore, it is considered, how uncertain such reports must have been, and also to what changes weights and measures are exposed from decay, accident, or design, it is not surprising that so much confusion should be experienced, especially in tables where no general revision has ever taken place.

The only comparison of the kind upon record is that made in 1767, by M. Tillet, at the Paris Mint, by order of the French government. His operations, however, were confined to money weights, and these only of a limited number of places. His tables, as far as they extend, have been generally used, although their accuracy is, in many instances, disputed, especially by Krufe, and other German writers. Nelkenbrecker, in his elaborate work on monies, weights, and measures, published at Berlin in 1810, gives a long statement (page 508.) of discrepancies between Tillet's reports and those of other assay masters.

But the most numerous and important errors are in the tables of commercial weights and measures; and therefore with a view of remedying an evil so perplexing to merchants, our government has recently issued an order to the British consuls abroad, to send home well-attested copies of foreign standard weights, that they may be accurately compared with those of England at his majesty's mint. Correct statements are likewise required of the mathematical dimensions of measures of capacity, and of their comparative contents, as estimated and acted upon by merchants.

We have authority further to state, that the plan was examined and approved by the Board of Trade, on the 14th of January 1818; and, by their lordships' recommendation, the order to the consuls has been issued from the foreign-office, by Viscount Castlereagh.

The copies of standards thus transmitted to London are to be weighed and compared by Robert Bingley, esq. F.R.S., the king's assay-master of the Mint; and the results of those important comparisons are to be published by Dr. Kelly, who projected the plan, and who will perform the calculations. The revised tables are expected to be brought out in the second edition of his *Cambist*; and should they be printed before our *Cyclopædia* is finished, we hope for the author's permission to insert them in our *Addenda*.

WEIGHTS.

Weights and Measures, in Agriculture and Rural Economy, are of great consequence to the land-owner and the farmer, as being the proportions or quantities by which various sorts of produce, of the agricultural and other such kinds, are disposed of and sold. They are found to vary very greatly in different districts and parts of the country, as well as in different places and towns of the same district or county, and even in the markets of the same town. Consequently, the confusion, uncertainty, inconvenience, and loss which are thus produced, are often very great and troublesome. We have already, in the preceding article, observed, that the two principal weights established in Great Britain are the troy and avoirdupois weights, and by these most of the articles of farm produce, and those of many other kinds, are sold in this country.

There are some, however, that are disposed of in other ways, as will be seen below.

However, as the diversity of weights and measures (in different places) creates much perplexity and uncertainty in the purchase as well as disposal of different sorts of produce, it would not only be highly desirable, but convenient and advantageous, to have one universal standard or system of weights and measures. For an account of the attempts that have been made to obtain such a standard, see **STANDARD.**

Different Weights and Measures for Farm and other produce by Troy Weight.

24 Grains	make	1 Pennyweight
20 Pennyweights	-	1 Ounce
12 Ounces	-	1 Pound.

By this weight are weighed gold, silver, amber, bread, corn, and all liquors.—14 oz. 11 dwts. 15½ grains, or 292 dwts. nearly, are equal to a pound avoirdupois.

By Avoirdupois Weight.

16 Drams	make	1 Ounce
16 Ounces	-	1 Pound
28 Pounds	-	1 Quarter
4 Quarters	-	1 Hund. weight
20 Hund. weight	-	1 Ton.

By this weight are weighed all the farm produce, such as butter, cheese, and many other articles; and all metals, except those of the finer kinds. In other cases,

7½ Pounds	make	1 Gallon of train-oil
8 Pounds	-	1 Stone of butcher's meat
14 Pounds	-	1 Stone of horseman's weight
19½ Hundreds	-	1 Fodder of lead.

In Wool Weight.

7½ Pounds	make	1 Clove
2 Cloves	-	1 Stone
2 Stone	-	1 Todd
6½ Todds	-	1 Weigh or Wey
2 Weys	-	1 Sack
12 Sacks	-	1 Last.

In Hay Weight.

56 Pounds of old hay, or	} make	1 Trufs
60 Pounds of new ditto		1 Load.
36 Trusses	-	-

In Bread Weight.

	lb.	oz.	dr.
A peck loaf weighs	-	-	17 6 ½
A half ditto	-	-	8 11 0
A quarter ditto	-	-	4 5 8

By Dry Measure.

2 Pints	make	1 Quart
2 Quarts	-	1 Pottle
2 Pottles	-	1 Gallon
2 Gallons	-	1 Peck
4 Pecks	-	1 Bushel
4 Bushels	-	1 Coomb
2 Coombs, or eight bushels	-	1 Quarter
4 Quarters, or 32 bushels in the country, and 36 in London	-	1 Chaldron
5 Quarters	-	1 Weigh or Wey
2 Weys, or 10 quarters	-	1 Last.

By this measure are measured corn, salt, lead, ore, oysters, different other such matters, and all dry goods. The standard Winchester bushel is a cylinder 18½ inches diameter, and 8 inches deep.

By Long Measure.

3 Barleycorns	make	1 Inchi
12 Inches	-	1 Foot
3 Feet	-	1 Yard
6 Feet	-	1 Fathom
5½ Yards	-	} 1 Pole, rod, or perch
40 Poles	-	
8 Furlongs	-	1 Mile
3 Miles	-	1 League
60 Geographical, or } 69½ English miles	-	1 Degree
360 Degrees	-	} The circumference of the Globe.

This comprehends length only, as in the above cases.

By Square Measure.

144 Square inches	make	1 Square foot
9 Square feet	-	1 Square yard
100 Square feet	-	1 Sq. of flooring
272¼ Square feet	-	1 Square rod
40 Square rods	-	1 Square rood
4 Square roods	-	1 Square acre
30 Square acres	-	} 1 Square yard of land
100 Square acres	-	
640 Square acres	-	1 Square mile.

Square measure comprehends length and breadth, and is used in measuring land, in paving, flooring, painting, glazing, plaistering, roofing, slating, tiling, and for several other rural purposes.

In land measuring is used Gunter's chain, which is 4 poles or 22 yards, or 66 feet long, and contains 100 links, each link being 7.92 inches long.

And 43560 square feet or 4840 square yards, or 160 square poles, that is, 160 poles in length and 1 pole in breadth, or 4 square roods, or 10 square chains, that is, 10 chains in length and 1 chain in breadth, make an acre of land.

By Cubic or Solid Measure.

1728 Cubic inches	make	1 Cubic foot
27 Cubic feet	-	1 Cubic yard
40 Feet of rough timber	}	1 Load
50 Feet of hewn ditto		

This comprehends length, breadth, and thickness.

M m

And

WEIGHTS.

And 108 solid feet, that is, 12 feet in length, 3 feet in breadth, and 3 deep, or commonly 14 feet long, 3 feet 1 inch broad, and 3 feet 1 inch deep, are a stack of wood.

And 128 solid feet, that is, 8 feet long, 4 feet broad, and 4 feet deep, are a cord of wood.

In Coal Measure.

4 Pecks	make	1 Bushel
3 Bushels	- - -	1 Sack
12 Sacks, or 36 bushels	- - -	1 Chaldron
21 Chaldrons	- - -	1 Score

In Corn Measure.

1 Load of corn	makes	5 Bushels
1 Laft of ditto	- - -	43 Do.

It is enacted by 31 George III., that a Winchester bushel of corn should weigh as follows :

	lb.		lb.	
Wheat	57	avoirdupois,	Wheat meal	56
Barley	49	- - -	Flour	48
Bigg	42	- - -	Ditto	41
Oats	38	- - -	—	32
Rye	55	- - -	—	53

} Flour, 45lb. of
} which should be
} equal to a Win-
} chester bushel
} unground.

After these statements of the different weights and measures which are in common use for different sorts of produce, it may not be improper to notice some of the differences of weights and measures, as they exist in different districts, towns, and parts of the kingdom, according to the account which has been given of them, and as they are injurious to the farmer.

In the counties or districts near the metropolis, the statute measures are pretty commonly employed, though there are many irregularities and deviations; but in those at some distance there are more frequent and remarkable variations and differences.

In the county of Middlesex, the weights and measures made use of are mostly those of the standard legal kind, and consequently the variations in them are but little.

Wood is sold by the stack, as packed three feet by three, and twelve feet long, containing in this manner 108 cubical feet.

Effex is now pretty much in the same state as above, in regard to its weights and measures, though formerly they varied very greatly, wheat being sold either by weight or measure, as agreed upon. The measure then eight gallons and a half the bushel; and the weight, that usually termed the peck weight, or the medium of what eight and a half of good wheat would weigh.

Then all other sorts of grain were sold by measure, but by that which was very different in different places, and for different sorts, the bushel of barley, malt, oats, &c. being often nine gallons; others eight and a half, and eight and three pints, &c. There are still some remains of these measures in the county. Various articles, too, are still sold there by the tale, the dozen, the score, and the hundred of six score, such as hop-poles, faggots, &c.

The writer of the Berkshire Agricultural Report remarks, that, notwithstanding the fines and forfeitures attached to selling corn by any other than the standard bushel, and the obvious ill consequences resulting from the practice without one counterbalancing advantage, that county, like most others, has its diversity of measures, which only encourages jobbers, to the prejudice of the grower of corn; who, influenced by habit, does not always take into consideration, that if he should sell nine gallons instead of eight

to the bushel, he is giving a bushel in every quarter of grain more than the laws allow, or justice requires, and that the dealer is probably making that proportion of profit, out of his ignorance or obstinacy.

The owners of land cannot, therefore, more effectually serve their tenants, it is supposed, than by exerting themselves to introduce an uniformity of measure in their respective neighbourhoods.

The nine-gallon bushel prevails in some parts of the county, but in others the standard. At Faringdon and Wantage, the former is almost exclusively used; but at Abingdon both it and the standard bushel are employed. The former is the custom of the market, however, unless the contrary be specified; but malt sold out of the town is only eight gallons measure.

Corn is commonly sold by the load of five quarters. In building, hedging, and ditching, the perch or pole of eighteen feet is the usual measure.

Wood is sold by the foot, and load-underwood by the cord, in some places absurdly called a load, and by the proper load.

Besides the statute acre, there are also common field acres, which are sometimes more, and sometimes less, than the statute.

In weights the diversity is great in most places.

In the county of Sussex, the weights and measures most commonly used are, the pound, stone, acre, load, bushel, &c. There are several sorts of acres, which are a great source of perplexity and confusion—the short acre, the statute acre, the forest acre, and various others: the forest acre is nine score rods; the statute, eight score; and the short acre, six score in some places, in others five score. The stranger, unaware of the variations that prevail in the weights and measures, is, it is said, liable to fall into mistakes in every step he takes; and that until a radical reform is brought to bear, the present confusion in buying and selling must prevail, and the honest and unsuspecting will be taken in by the crafty and designing.

In the other southern districts or counties, the variations in their weights and measures are much the same, though less than in those of the north.

It is stated in the Gloucester Report on Agriculture, that in the market of that town, the bushel varies from nine to ten gallons; in the forest district it is nearly ten gallons; on the Cotswolds about nine; in the vale nine and a half; and in the lower vale, and at Cirencester, nine and a quart, of all sorts of grain.

Near Bristol, potatoes, green peas, &c. are sold by the double peck, containing two common ones struck level with the top; while at Gloucester, and higher up the vale, it is a common peck heaped up. Wool is generally sold by the stone weight of 12½lbs., or the tod of 28½lbs. Butter often by the pound of 18 oz.; and the quart of about 3lbs.

In Herefordshire the peculiar weights and measures which are at present in use are these, according to the Survey on Agriculture for that district.

1 Pound of fresh butter	-	18 Ounces
1 Stone	- - -	12 Pounds
1 Customary acre	- - -	$\frac{2}{3}$ Of a statute acre
1 Hop acre	- - -	That space of ground which contains 1000 plants; viz. about $\frac{1}{2}$ a statute acre
1 Lugg	- - -	49 Square yards of cop-pice-wood

Wood

WEIGHTS.

1 Wood acre	-	-	$\frac{3}{8}$ Larger than a statute, <i>i. e.</i> as 8 are to 5
1 Day's math	-	-	About a statute acre of meadow or grass land, being the quantity usu- ally mown by one man in one day
1 Perch of fencing	-	7	Yards
1 Perch of walling	-	16 $\frac{1}{2}$	Feet
1 Perch of land	-	5 $\frac{1}{2}$	Yards (as statute)
1 Bushel of grain	-	10	Gallons
1 Bushel of malt	-	8 $\frac{1}{2}$	Gallons.

In the Report on Agriculture for Shropshire, it is stated, that wheat, barley, and peas, are sold by the strike or bushel, which, in Shrewsbury market, is 38 quarts, but in some other markets it is 40 quarts. That the 38 quarts of wheat should weigh 75lbs., the 40 quarts 80lb. In other markets in the county, the bushel of wheat does not weigh more than 70lbs.: this is chiefly applicable to the eastern district of the county. The bushel of flour is every where 56lbs. That 38 quarts of barley weigh about 65lbs. That a bushel of oats means three half bushels of the customary measure at Shrewsbury, and should weigh better than 93lbs. But that in other markets it means 2 $\frac{1}{2}$ bushels, sometimes heaped, sometimes stricken, and sometimes a medium between both. That a bag of wheat means three bushels customary measure. The quarter bushel is called a hoop or peck; and the fourth of that is called a quarter. Butter, when fresh, weighs 17oz. to the pound; when salted, 16 oz. The last is reckoned by the gawn, which signifies 12lbs. of 16 oz. in Shrewsbury, and 16lbs. of 16 oz. at Bridgnorth. Cheese is sold by the cwt., which, at Shrewsbury, means 12lbs., and 113lbs at Bridgnorth. Coals are sold by the ton, which is 20 cwt. of 112lbs. at some pits, and 120lbs. at others: the stack is now rarely used; it was a measure of four feet square, and would sometimes weigh 25 cwt. Hay is sold by the ton, of 20 cwt. of 112lbs. Home-made linen cloth is sold by the ell, which measures a yard and a half; and it is added, that the acre is the statute acre. That the workman's rood in digging is eight yards square; but in hedging eight yards in length.

It is suggested, too, that there is an error in the standard measure, that in the Exchequer not agreeing with the requisitions of the 13 Will. III. c. 5. By which statute, the bushel is ordered to be 18 $\frac{1}{4}$ inches round, and 8 deep; it would consequently contain

Cubic inches	-	-	-	-	2150
That in the Exchequer contains	-	-	-	-	2124
Eight of the standard gallons	-	-	-	-	2168
Thirty-two ditto quarts	-	-	-	-	2240
Sixty-four ditto pints	-	-	-	-	2027

That the difference between the bushel and 32 of the quarts is, therefore, 116 cubic inches, or nearly three pints and a half.

It is stated, too, that in the northern part of the North Riding of Yorkshire, the customary bushel exceeds that of the Winchester, by full two quarts; but nearer to the southern extremity, seldom by more than one: the bushel of some individuals in the Riding is still larger, measuring about 10 *per cent.* more than the statute requires.

And further, that a stone of wool in York market is sixteen pounds, and four ounces in each stone are allowed for draught; that is, for the draught of each fleece, the wool-buyers being empowered by act of parliament to weigh each fleece *separately*, if they like. That at Ripon market,

a stone of wool is 16 pounds 12 ounces. And a stone of wool in the Western Moorlands is 17 $\frac{1}{2}$ pounds; the half pound, the writer apprehends, is for draught, as in York market.

But that at Darlington, where the wool grown about Richmond in that district is chiefly fold, the stone is 18 pounds. And that in the Eastern Moorlands, the weights used by individuals vary up to 19 pounds to the stone.

That the pound of butter in the Riding varies from 16 to 24 ounces. But that a stone of all other commodities throughout the whole of it is 14 pounds.

In Cheshire, though the variety in the weights and measures is very considerable, it is less on the whole than in some other parts of the country.

The weights in this district are usually the avoirdupois 112lbs. to the hundred weight. Some articles are sold by what is called the long hundred of 120lbs. Cheese is one of these. Hay, too, is generally there sold by the cwt. of 120lbs.

Butter, in most parts of the county, is disposed of by the pound weighing 18 ounces. In some places it is sold in lumps, made up in moulds of different forms, called dishes, or half dishes. These weigh 24 or 12 ounces each.

Potatoes are usually disposed of by the bushel weighing 90 pounds.

Wheat by the bushel weighing either 70 or 75 pounds.

Oats by the bushel weighing from 45 to 50 pounds, as the price and bargain may be.

Oatmeal by the load weighing 240 pounds.

Barley is sometimes sold by the bushel of 60 pounds, and sometimes by the measure of 38 quarts.

Malt by the measure of 32 or 36 quarts.

Land was formerly very generally measured there by what is called the Cheshire acre, containing 10,240 square yards; and this measure still continues to be used to a certain extent, particularly in the northern part of the county. The statute acre is now, however, it is said, in much more general use.

A rood of land is 64 yards. A rood of hedging, ditching, and other such operations, eight yards in length. And a rood of marl is 62 cubic yards.

In the Lancashire Report on Agriculture, it is observed, that the rod is of no less than six different lengths in different parts of the county; namely, the statute, or 5 $\frac{1}{2}$ yards, 6, 6 $\frac{1}{2}$, 7, 7 $\frac{1}{2}$, and 8 yards, to the rod, pole, or perch: and that the measures are equally variable. At Lancaster a load of wheat, beans, and peas, is four and a half bushels (Winchester); barley, six Winchester bushels; oats, seven and a half Winchester bushels: they have also a measure called a *windle*, which is equal to three Winchester bushels. But that wheat has been sold lately by the weight of 280lbs.

That at Ulverstone, a load of wheat is four and a half Winchester bushels; oats, six Winchester bushels. And that at Manchester, a load of wheat is sixteen score; a load of oats, nine Winchester bushels; a load of beans, five Winchester bushels; a load of potatoes, twelve score and twelve pounds, washed; unwashed, thirteen score. That Liverpool town's bushel is 34 $\frac{1}{2}$ quarts for oats, barley, and beans, making exactly 36 quarts Winchester, or one-eighth more than a Winchester bushel, and by the custom of trade, one given in at every score, or twenty-one bushels; of late, wheat, barley, and oats, have been sold by weight, but never yet beans; wheat, 70lbs. to the bushel; barley, 60lbs.; and oats, 45lbs.: and probably this mode by weight is the fairest for both a buyer and seller; for, besides the difficulty of getting a true standard bushel or measure, the dexterity

WEIGHTS.

of corn-measures is such, that it is asserted they can gain either to the buyer or seller from 10 to 20 per cent. in different modes of measurement; that 5 per cent. can be obtained by this practice, by even bunglers in the business: this is an enormous profit, and the unfairness of such practices merits the severest reprehension.

That at Preston the windle of wheat, beans, and barley, is three and a half Winchester bushels; but of late 220lbs. have been reckoned a windle of wheat: they have also a measure there called a peck, which is twenty-eight quarts, four of which are called a windle.

In respect to weights, there are three different ones expressed under the general term hundred weight; namely, 100lbs., 112lbs., and 120lbs. The stone, too, varies. In Liverpool, 20lbs. are the weight allowed for the several articles under that denomination, as beef, hay, straw, &c.; and probably all the articles produced from land. And butter is required to weigh 18 ounces avoirdupois, or it may be seized by the magistrates.

At Lancaster, and the neighbourhood, they have several different weights, as the Lancaster peck, of twenty-four quarts; the common peck, of sixteen quarts; the half Winchester; the windle, of three and a half bushels; the met, of fifty-six quarts; the ackendale, or ackentyde, the eighth part of the above, or seven quarts, and the measure of four quarts. The load of malt is six bushels.

Butter eighteen ounces to the pound; other articles fifteen.

There are also different local variations in many articles.

In Westmoreland, the pound consists of twelve, sixteen, eighteen, or twenty-one ounces; and the stone of fourteen, sixteen, or twenty pounds. There is also a Winchester bushel, a customary bushel equal to three of these, a bushel of two bushels for the sale of potatoes near Appleby, and one of two and a half for that of barley. Rye is sold by the boll of two bushels, and potatoes by the load of four bushels and a half heaped; or more generally a bag, which holds seven and a half bushels, is filled and sold for a load of potatoes.

There is the statute acre, too, of 4840 square yards, the customary acre of 6760 raised from the perch of six and a half yards, and a third acre on the borders of Lancashire, raised from the perch of seven yards, containing 7840, being the same as the Irish plantation acre.

It is remarked, likewise, in the Cumberland Report on Agriculture, that the same confusion in weights and measures prevails there, as in many other parts of the kingdom.

That a Winchester bushel is thirty-two quarts; a Carlisle bushel, ninety-six quarts; and a Penrith bushel, sixty-four quarts, for wheat and rye; and eighty quarts, for barley, oats, and potatoes.

That a stone of tallow, wool, yarn, or hay, is 16lbs.; and a stone of butcher's meat 14lbs., but in many places 16lbs.

That the pound is sixteen ounces, by which butter and various other articles are weighed.

The writers of the Account of Agriculture for Northumberland, state that their weights and measures are in a sad state of confusion; a pound, a stone, a bushel, and a boll, are rarely the same in different markets, and frequently vary in the same market for different articles.

At Newcastle.

That a stone of wool in some parts is 24lbs.; in others, 18lbs.; and a stone of every other article is 14lbs.

As the weights and measures made use of in Scotland differ very materially from those employed in England, it may, of course, not be useless to give a cursory view of them under the present head. It has been observed by Mr. Somerville, in his Account of the Agriculture of East Lothian, that land is measured by the Scotch acre, which is to the English acre very nearly in the proportion of five to four.

That the boll is the denomination of corn measure always used, but the contents vary according to the species of grain measured. But that there are uniformly four firlots in the boll of all grain; but the firlot differs in size in the proportion of 21, 25, to 31. Wheat, rye, beans, and peas, are sold by the small firlot; malt, barley, and oats, are sold by the large one. Four small firlots are 4.087276 Winchester bushels; four large ones are 5.96263 bushels Winchester. The boll of wheat then is a small fraction more than half a quarter; and the boll of barley, a fraction less than three-fourths of a quarter. But this calculation applies, it must be remembered, to the Linlithgow boll, which is accounted the standard measure of Scotland: the measure actually used in East Lothian is somewhat larger.

In the Mid-Lothian Report on Agriculture, it is stated, that flour, pot-barley, groceries, iron, and ropes, are bought and sold there, by what is termed English weight, being 16 oz. to the pound, and 16lbs. to the stone. But that butcher's meat, oatmeal, and flax, are bought and sold by what is called Dutch weight, of which the proportion to the English is as 17½ to 16.

That wool, hay, and butter, are bought and sold by trone weight, of which the proportion is to the English, as 22 to 16. That other articles are bought and sold by either of these weights, as it may happen.

But that in long measure the inch is the root, of which 12 go to the foot, and 37 to the Scotch yard.

And that land is measured by a chain 24 yards in length, or 74 feet, divided into 100 links, of 8.888 inches each in length; 10 square chains make an acre, or 5760 square yards Scotch, equal to 6084.444 English; and as the

WEIGHTS.

the English acre consists of 4840 square yards, hence the proportion that the Scotch acre bears to the English is, with a small fraction more, as 5 to 4, as seen above.

That in liquid measure the *pint* is the root, containing 103.404 cubic inches; the half and quarter in proportion.

That the Linlithgow wheat firloft, the only standard measure for that grain in Scotland, contains $21\frac{1}{4}$ pints; hence in cubic inches 2197.34. The Winchester bushel, in like manner the English standard, contains 2150.42 cubic inches; hence the Scotch wheat firloft is about $2\frac{1}{7}$ per cent. greater than the English bushel.

And the Linlithgow barley measure, which is likewise the standard, contains 31 pints, or 3205.54 cubic inches; hence $5\frac{2}{3}$ bushels are very nearly equal to the Scotch boll of 4 firlofts.

That straw is fold by tale, 40 windlens to a kemple, generally from 14 to 16 stone trone weight.

It is noticed, that in East Lothian, meal is fold by the peck of eight pounds Amsterdam weight; and that the boll of meal contains sixteen pecks or eight stones.

It is stated in the Clydesdale Report on Agriculture, that in the dry measure, used in the sale of grain of all kinds, a boll contains four firlofts, a firloft four pecks, and a peck four forpits or lippies; 16 bolls make a chaldier. The firloft used to measure barley and oats, is almost one-half larger than the firloft for measuring wheat, beans, peas, &c. That both these measures are about one-sixteenth larger than the Linlithgow standards of the same denominations. But for more than thirty years past, wheat has been bought and sold by the Linlithgow standard, which is now attempted to be introduced for other grains.

That in the lower parts of the county potatoes have been measured, for these forty years, with a dish of the shape of a cask, the peck measure holding fifteen Scotch pints; its weight, full of potatoes recently dug, is 43lbs. avoirdupois. In the higher parts of the county potatoes are sold by the barley measure.

That the peck, or *sheek*, for measuring pears and apples, holds about eighteen pints. The confusion occasioned by the irregularity of weights and measures, is too obvious, the writer says, to require any comment.

In the Argyshire Agricultural Report, it is said that at Inverary the boll of meal is eight stone Scotch troy, or Dutch 17 $\frac{1}{2}$ lbs. avoirdupois to the stone. At Campbelton it is ten stone, of the same weight; or sixteen pecks of 10lbs. Scotch troy, or 10lbs. 15 oz. avoirdupois each.

That in some parts of the Knapdale and Lorn, the boll is nine stone. That in the first of the above places, oats, barley, and malt, are measured by a firloft of 3438.183 cubic inches; equal to one firloft, two pints, one mutchkin, Scotch standard measure, which makes the boll (of four firlofts) 7.258 per cent. better than the Scotch standard measure, and equal to six bushels, one peck, nine pints, 10.2 cubic inches, English standard measure.

And that in Kintyre, oats, barley, or bear and malt, were, for time immemorial, sold by a heaped peck, of which the standard lay with the dean of Guild in Campbelton. Of this measure, seventeen pecks made, and still make, the Kintyre boll from August to Patrickmas, and only sixteen from that date to the new crop; and the divisions of the boll are regulated by the same proportions. But from the inconvenience of measuring by the heaped peck, it has been

converted into the striked one containing the same quantity; and this new striked peck committed to the dean of Guild, has been since the standard of the district. The dimensions of it are twelve English inches diameter, equally wide throughout, and ten and a tenth English inches deep. The contents of it in cubic inches are 1142.28576, equal to eleven Scotch pints, and a very little more than two-thirds of a gill, which makes the Kintyre boll 19418.85792 cubic inches, before Patrickmas, and 18276.57216 after it. A lippie more, or $\frac{1}{4}$ th of a boll, for town dues, is given with every boll delivered in Campbelton. The first is equal to nine Winchester bushels, and 65.03112 cubic inches, (about $\frac{3}{7}$ of a bushel) and equal to one boll eight pecks, 1.61788 lippie, Linlithgow standard measure. The latter is equal to eight and a half Winchester bushels, excepting 2.0394 cubic inches, and to one boll six pecks, $3\frac{2}{3}$ lippies Linlithgow. The Winchester bushel contains 2150.42 cubic inches. The Linlithgow boll standard measure 12822.096.

That at Inverary, the peck of potatoes contains fourteen pints and one mutchkin, ale measure. At Campbelton, it contains about nine English wine gallons, and is given heaped; and generally weighs about 56lbs. avoirdupois.

But that beans and peas are sold in Kintyre by the old peck striked, or by a measure one-third less than that for oats and bear. Lineal and liquid measures are the same with the Scotch standards. Butter, cheese, tallow, hay, wool, and lint, are sold by the stone of 24lbs. avoirdupois. Butcher's meat by the pound of twenty-four ounces avoirdupois at Inverary, and of sixteen ounces at Campbelton. The herring-barrel contains thirty-two English gallons of wine measure, or 67.28 customary ale pints of 109.866 cubic inches each.

These facts and statements sufficiently shew the necessity of some regulation being speedily adopted of adjusting weights and measures to some simple standard, both in this and the northern parts of the kingdom.

The table of weights constructed by lord Somerville, and introduced below, may be useful to the stock-farmer and grazier in most situations.

TABLE for the Equalization of different Weights.

WEIGHT, *Pondus*, in *Mechanics*, is any thing to be raised, sustained, or moved by a machine; or any thing that in any manner resists the motion to be produced. See **MOTION**, &c.

In all machines, there is a natural ratio between the weight and the moving power. If the weight be increased, the power must be so too; that is, the wheels, &c. are to be multiplied, and so the time increased, or the velocity diminished.

“The centre of gravity *F*, (*Plate XL. Mechanics, fig. 6.*) of a body *I H*, together with the weight of the body, being given; to determine the point *M*, in which, lying on a horizontal plane, a given weight *G*, hung in *L*, cannot remove the body *I H* out of its horizontal situation.”

Conceive a weight hung in the centre of gravity *F*, equal to the weight of the whole body *I H*, and find the common centre of gravity *M*, of that and the given weight *G*. If the point *M* be laid on the horizontal plane, the weight *G* will not be able to move the body *H I* out of its place.

“The centre of gravity *C* (*fig. 7.*) of a body *A B*, together with its weight *G*, being given; to determine the points *L* and *M*, wherein props *M N* and *L O* are to be placed, that each may bear any given proportion of the weight.”

In the horizontal line *A B*, passing through the centre of gravity *C*, assume the right lines *M C* and *C L* in the given ratio. Props, then, *M N*, *L O*, placed in these points, will be pressed in the given ratio.

Hence, if in the points *M*, *L*, in lieu of props, you place the shoulders or arms of porters, &c. they will be able to bear the burden alike; if their shares be proportioned to their strengths. Thus we have a way of distributing a burden in any given ratio.

WEIGHTS, *Gros, Neat, Penny, Assay of, Ancel.* See the several articles.

WEIGHT of the Atmosphere. See **ATMOSPHERE**.

WEIGHT of the Air, is equal to the elasticity thereof.

To find the *Weight of a Cubic Inch of Air*.—Weigh a round glass vessel full of common air, very accurately; then exhaust the air out of it; weigh the exhausted vessel, and subtract the latter weight from the former, the remainder is the weight of the air exhausted.

Find, then, the content of the vessel by the laws of measuring; and the ratio of the remaining air to the primitive air. This done, the bulk of the remaining air is found by the rule of three; which being subtracted from the capacity of the vessel, the remainder will be the bulk of air extracted. Or, if the air-pump be very tight, and the exhaustion continued as long as any air is got out, the remaining air will be so small, that it may be very safely neglected, and the content of the vessel taken for the bulk of the exhausted air.

Having, therefore, the weight and bulk of the whole exhausted air, the weight of one cubic inch is easily had by the rule of three.

This method was first used by Otto Guericke, and afterwards by Burcher de Volder, who gives us the following particulars in his experiment. 1. That the weight of the glass spherical vessel he made use of, full of common air, was 7 lbs. 1 oz. 2 drs. 48 grs.; when exhausted of air, 7 lbs. 1 oz. 1 dr. 31 grs.; and when full of water, 16 lbs. 12 oz. 7 drs. 14 grs. The weight of the air, therefore, was 1 dr. 17 grs. or 77 grs.; the weight of the water 9 lbs. 11 oz. 5 drs. 43 grs. or 74743 grs. Consequently, the ratio of the specific gravity between water and air is 74743 : 77 :: 970 $\frac{5}{7}$: 1. Now, De Volder having found a cubic foot of water to weigh 64 lbs., by inferring, as 970 is to 1, so is 64 lbs. to a

fourth proportional, deduced by the rule of three, the weight of a cubic foot of air, viz. 1 oz. 27 grs. or 507 grs. nearly. Wolfii Elem. tom. ii. p. 291.

From other later experiments accurately made with the hydrostatical balance, a cubic inch of air appears to be equal to two-sevenths of a grain, and therefore a cubic foot equal to 493 $\frac{5}{7}$ troy grains. There are various ways of estimating the weight of the air; for which, see **AIR**, **ATMOSPHERE**, **BAROMETER**, **Specific GRAVITY**, &c.

It may be easily determined by fitting a brass cap, with a valve tied over it, to the mouth of a thin bottle or Florence flask, whose contents are exactly known, and screwing the neck of this cap into the hole of the plate of the air-pump; then, having exhausted the flask of its air and taken it off from the pump, suspend it at one end of a balance, and nicely counterpoise it by weights in the scale at the other end: when this is done, raise up the valve with a pin, and the air will rush into the flask, and cause it to descend. When it is full of air, put grains into the scale at the other end to restore the equilibrium; and if the flask holds exactly a quart, it will be found, that 17 grs. will be sufficient for this purpose, when the quicksilver stands at 29 $\frac{1}{2}$ inches in the barometer; and this shews, that when the air is at a mean ratio of density, a quart of it weighs 17 grs.; and consequently a gallon weighs 68 grs.: i. e. 231 cubic inches of air are equal in weight to 68 grs., and 1728 cubic inches, or a cubic foot of air, weighs 509 $\frac{5}{7}$ grs.; and as a cubic foot of water weighs about 437702 troy grains, the specific gravity of water will appear to be more than 850 times that of air. See **AIR**.

The weight of *sea-water* is different in different climates. Mr. Boyle having furnished a learned physician, going on a voyage to America, with an hydrostatical balance, and recommended him to observe, from time to time, the difference of weight he might meet withal; this account was returned him: that the sea-water increased in weight, the nearer he came to the line, till he arrived at a certain degree of latitude, as he remembers, about the 30th; beyond which, it retained the same specific weight, till he came to Barbadoes. Philof. Transf. N^o 18.

The weight of a cubical inch of good brandy, rum, or other proof spirits, is 235.7 grs.; therefore, if a true inch cube of any metal weighs 235.7 grs. less in spirits than in air, it shews the spirits are proof; if it loses less of its aerial weight in spirits, they are above proof; if it loses more, they are under: for the better the spirits are, they are the lighter; and the worse, the heavier.

As all bodies expand with heat and contract with cold, in different degrees, the specific gravities of bodies are not precisely the same in summer as in winter. It has been found, that a cubic inch of good brandy is 10 grs. heavier in winter than in summer; as much spirit of nitre, 20 grs.; vinegar, 6 grs.; and spring-water, 3 grs. Hence it is most profitable to buy spirits in winter, and sell them in summer, since they are always bought and sold by measure. It has been found, that 32 gallons of spirits in winter will make 33 in summer. Ferguson's Lect. p. 98. 4to. See **Specific GRAVITY**, and **HYDROMETER**.

WEIGHT of the Human Body. It is to be observed, that the heat and dryness of the air both lessen the weight of the body, and the cold and moisture of the air both increase this weight. See **MOISTURE**.

Much sleep, much food, and little exercise, are the principal things which increase the weight of the body, and make animals grow fat. Consequently, if the weight of the body be too great for good and uninterrupted health, it may be lessened by diminishing sleep and food, and by increasing

creasing exercise. On the contrary, if the weight of the body be too little for good health, it may be increased by adding to food and sleep, and by lessening exercise; and the food must be increased chiefly by increasing drink and liquid nourishment. For the discharges are commonly less from drink and liquid nourishment, than from dry and solid food.

There is but one weight under which a body can enjoy the best and uninterrupted health, and that weight must be such, that perspiration and urine may be nearly equal at all seasons of the year; for by this means the body will be uniformly drained of its moisture: the inward parts by urine, and the more superficial parts by perspiration, without any irregular and unnatural discharges, and its moving weight will continue nearly the same at all seasons of the year. Dr. Bryan Robison thinks this weight may be settled by his observations in his Treatise on Food and Discharges of Human Bodies.

A quick increase of weight in human bodies often produces distempers; the best way to prevent this increase is either by fasting or exercise. But amidst a variety of disturbing causes, nothing so effectually prevents such an increase of weight as a very exact and regular diet, which may prevent the discharges from running into irregularities and disproportions to one another. See Dr. Bryan Robison of the Food and Discharges of Human Bodies, p. 82. seq.

Men, and other animals of extraordinary weight, are often recorded in the writings of the learned. See Phil. Trans. N^o 479, p. 102.

WEIGHT, Athletic, in the *Animal Economy*, that weight of the body under which an animal has the greatest strength and activity. Dr. Robison thinks this happens when the weight of the heart, and the proportion of the weight of the heart to the weight of the body, are greatest. For the strength of an animal is measured by the strength of its muscles, and the strength of the muscles is measured by the strength of the heart. Also the activity of an animal is measured by the weight of the heart, in proportion to the weight of the body.

If the weight of the body of an animal be greater than its athletic weight, it may be reduced to that weight by evacuations, dry food, and exercise. These lessen the weight of the body by wasting its fat, and lessening its liver, and they increase the weight of the heart, by increasing the quantity and motion of the blood; so that by lessening the weight of the body, and by increasing that of the heart, they will soon reduce the animal to its athletic weight. Thus a game cock, in ten days, is reduced to its athletic weight, and prepared for fighting. If the food which, with the evacuations and exercise, reduced the cock to its athletic weight in ten days, be continued any longer, the cock will lose his strength and activity.

It is known by experience, that a cock cannot stand above twenty-four hours at his athletic weight, and that he has even changed for the worse in twelve hours. When he is in the best condition, his head is of a glowing red colour, his neck thick, and his thigh thick and firm; the day after, his complexion is less glowing, his neck thinner, and his thigh softer; and the third day his thigh will be very soft and flaccid. Four game cocks, reduced to their athletic weight, were killed, and found to be very full of blood, with large hearts, large muscles, and no fat.

It is to be observed, that the athletic weight of an animal is a very dangerous weight. Fevers and apoplexies are the disorders which commonly happen to animals under or near the athletic weights. Hence, horses fed upon dry food are

much more subject to fevers and apoplexies than horses fed upon grafs. Robinson's Dissertation, p. 117, &c.

WEIGHTS, Sessions for. See SESSIONS.

WEIGHT, Live and Dead, of Animals, in *Agriculture and Rural Economy*, the differences between their living and dead weights as affecting their goodness and value for the purpose of the breeder and feeder or fatterer. But few correct trials have yet been made in the view of determining this very important point or particular. It would seem, however, from the little that has been done on the subject, that those sorts of live-stock that have the best forms, and the least weight in the different offal parts, are the most valuable and beneficial to the stock master and farmer.

In neat cattle stock the difference or loss in this way is somewhere about a fourth, but the most in those breeds which are the least correct in their forms or shapes. In some unimproved breeds it has been found a good deal more, while in those which have been greatly improved rather less. In calves it will mostly be from a third to a fourth.

In the good Herefords, and some of the best long horn or Lancashire sorts, these proportions have been found on trial to be very nearly correct, both in the grown beasts and the calves.

In sheep stock, too, the same principle, for the most part, holds good, those having the least difference or loss in this way that are the best in their forms.

In trials with the South Down breed of sheep, as stated in the Corrected Report on the Agriculture of the County of Suffex, the proportions of the live and dead weight are these:

	lbs.
Live weight of the sheep - - -	192
Dead weight next day of carcase - -	125

Weight of Offal.

	lbs.	oz.
Blood - - - - -	6	0
Entrails - - - - -	11	0
Caul - - - - -	16	4
Gut fat - - - - -	5	0
Head and pluck - - - - -	8	12
Pelt - - - - -	15	12

In an average specimen of a wether of the same breed:

	lbs.
Live weight of the sheep - - -	133
Dead weight the day after - - -	73

Weight of Offal.

	lbs.
Blood - - - - -	4
Tallow - - - - -	10
Entrails - - - - -	14
Skin and feet - - - - -	16
Head and pluck - - - - -	9

In one of general Murray's breed of the same kind:

	lbs.
Live weight - - - - -	129
Dead weight - - - - -	62

Weight of Offal.

	lbs.
Tallow - - - - -	6

It is remarked that the lightness of the offal, such as the head, horns, feet, entrails, pluck, blood, pelt, &c. is the circumstance which characterizes a good sheep; and it is said,

faid, that Dishley wethers well fattened are in the proportion of one ounce of bone to a pound of flesh.

That the offal, in the fat wether of the South Down breed first flated, was but a fifth part and a fraction of the live weight, as below :

	lbs.	oz.
Live weight - - - -	192	0
Offal - - - - -	42	0
Carcafe - - - - -	125	0
Fat - - - - -	21	4
Loft by killing - - -	3	12
	192	0

Some useful information, which has a tendency to elucidate the point concerning the proportion between the live and dead weight of some different breeds of sheep, has been given under the head sheep. See SHEEP, PELT, and TALLOW.

In good pig flock the difference in the proportion between the live and dead weight of the animals, or the loss of weight that is sustained by the farmer, will be found probably to be rather less than a fourth in the better breeds, and rather more than that in those which are inferior in their qualities. The best breeds of pigs have by much the least loss in this way, and they have advantages in other respects. See SWINE.

These facts and statements tend to shew the advantages which the farmer has in keeping good live-stock of all kinds.

WEIGHTON, MARKET, in *Geography*, a small market-town in the Holme-beacon division of Harthill wapentake, East Riding of the county of York, England, is situated on a little river called Foulness, in the high road between York and Hull, at the distance of 19 miles E.S.E. from York, and 192 miles N. by W. from London. Some antiquaries considered this place the Roman station, Dolgovitia, till Drake, with great appearance of probability, assigned that station to the village of Londesburgh, nearly three miles north of Weighton. This town consists of one long street, intersected by a few smaller: till within the last thirty years, the houses were in general low and mean, and covered with thatch; but since that period, a number of respectable buildings have been erected, and considerable improvements have been made. A weekly market is held on Wednesdays, when a great quantity of corn is often sold, though but little is exposed, being chiefly disposed of by sample. Two fairs are held annually for horses, cattle, and particularly for sheep, and cheese. The trade of the town has been considerably increased by means of a canal from the Humber; whereby coals and other articles are brought hither, and the barges return laden with grain. By the population return of the year 1811, the inhabitants of this town are enumerated at 1508; the number of houses as 239. The church is an ancient massive edifice; it formerly had a wooden spire, which has been recently taken down, and a considerable addition made to the height of the tower; the interior of the church has also been greatly improved, and furnished with an additional gallery. A meeting-house for Methodists has lately been erected. There is no endowed school in the parish. About two miles east of Weighton is the brow of the Yorkshire wolds, whence very extensive views are obtained.—Beauties of England and Wales, vol. xvi. Yorkshire, by J. Bigland, 1812. Drake's Eboracum, or the History and Antiquities of York, fol. 1736.

WEIGSDORF, a town of Bohemia, in the circle of Boleslaw; 8 miles N.N.E. of Krotttau.

WEIGSTOTTEN, a town of Austria; 6 miles N.W. of Steyr.

WEIKENDORFF, a town of Austria; 8 miles S. of Zisterdorf.

WEIKERSTORF, a town of Austria; 4 miles S.W. of Sonneberg.

WEIKERTSCHLAG, a town of Austria; 8 miles W. of Drofendorf.

WEIL, a town of Wurtemberg, on the Wirm. This was an imperial town, till in 1802 it was given to the duke of Wurtemberg, by whose dominions it was surrounded; 10 miles W.S.W. of Stuttgart. N. lat. 48° 48'. E. long. 8° 50'.

WEILACH, a river of Bavaria, which runs into the Par, near Schrobenhausen.

WEILBACH, a river of Germany, which runs into the Lahn, 2 miles S. of Weilburg.

WEILBURG, a town of Germany, which gives name to a county belonging to the house of Nassau, hence called Nassau Weilburg, situated on an eminence on the Lahn, over which it has a bridge of stone. The prince's palace here contains some very elegant apartments; with a fine garden belonging to it, and a chapel answerable to the whole. All the roads near the town lie in a direct line, and are planted on each side with a row of trees. In the neighbourhood is a large menagerie; 9 miles W. of Wetzlar. N. lat. 50° 26'. E. long. 8° 18'.

WEILE, or WEDEL, a sea-port town of Denmark, in North Jutland, situated on a bay in the Little Belt; 38 miles N.E. of Ripen. N. lat. 55° 45'. E. long. 9° 30'.

WEILHAIM, or WEILHEIM, a town of Bavaria; 26 miles S.W. of Munich. N. lat. 47° 44'. E. long. 11° 4'.

WEILHEIM, a town of Wurtemberg, on the Lauter; 20 miles N.E. of Ulm. N. lat. 48° 33'. E. long. 9° 35'.

WEILKO STRZLCZE. See STRELITZ.

WEILMUNSTER, a town of the principality of Nassau Weilburg; 5 miles S. of Weilburg.

WEILNAU, a town of Germany, in the principality of Nassau Weilburg; 13 miles S. of Weilburg.

WEILTINGEN, a town of Wurtemberg, on the Warnitz; 40 miles S.W. of Nuremberg. N. lat. 49° 3'. E. long. 10° 30'.

WEIMAR, a principality and duchy of Saxony, situated in Thuringia, on the sides of the Ilm; about 24 miles in length, and 20 in breadth, but considerable tracts are detached from the main body.—Also, a town of Saxony, and capital of a duchy of the same name, with a palace of the prince, in which the duke has a valuable library, a cabinet of medals, a museum, and a gallery of paintings; and where are kept the archives of the Ernestine line of the dukes of Saxony; 94 miles W. of Dresden. N. lat. 51° 2'. E. long. 11° 22'.

WEINBERG, a town of Austria; 4 miles S.E. of Freyftadt.—Also, a town of the principality of Anspach; 3 miles N.N.E. of Feuchtwang.

WEINFELDEN, a town of Switzerland, in the canton of Zurich, and principal place of a bailiwick, in the Thurgau; 4 miles S.W. of Constance.

WEINGARTEN, a town of the duchy of Baden; 13 miles S.S.E. of Spire. N. lat. 49° 3'. E. long. 8° 30'.

WEINGE, a town of Sweden, in the province of Halland; 12 miles S.E. of Halmstad.

WEINHAUSEN, a town of Westphalia, in the principality of Luneburg Zell; 6 miles from Zell.

WEINHEIM, a town of the duchy of Baden, situated in the Bergstrasse, and famous for its wine. The Roman Catholics, the Lutherans, and the Calvinists, have each a church; 9 miles N. of Heidelberg.

WEINITZ, or VINIZA, a town of the duchy of Carinola, on the Kulp; 10 miles E.N.E. of Gotschee.

WEINMANNIA, in *Botany*, a name which seems to have originated with Dr. Patrick Browne, who, without due attention, called it *Windmannia*. The person whom he designed to commemorate was John William Weinmann, an apothecary of Ratisbon, author of a huge botanical German work, entitled *Phytanthozaiconographia*, consisting of four thick folios, with 1025 large coloured engravings of plants. The first volume appeared in 1737, the last in 1745, after the author's decease. There is a preface to the latter by Haller. Dieterich and Bieler contributed part of the text, and there are ample indexes, in various languages. The plates are rude, and gloomily coloured. Trew, whose candour nevertheless is allowed by Haller, says, "varieties are not distinguished," in this work, "from species, the structure of the flowers is scarcely expressed, nor was the author competent to refer his plants to their true genera." Burmann began a Dutch edition, with some additions, in 1736. The book is necessarily expensive, on account of its bulk, and is rare in England. We have seldom had occasion to consult it, nor have we ever done so without disappointment.—Linn. Gen. 195. Schreb. 263. Willd. Sp. Pl. v. 2. 436. Mart. Mill. Dict. v. 4. Juss. 309. Poir. in Lamarck Dict. v. 7. 578. Lamarck Illustr. t. 313. (*Windmannia*; Browne Jam. 212.)—Class and order, *Oelandria Digynia*. Nat. Ord. akin to *Saxifraga*, Juss.; or rather, we should think, as he himself hints, to his *Rhododendra*.

Gen. Ch. *Cal.* Perianth inferior, of four ovate, spreading, permanent leaves. *Cor.* Petals four, equal, undivided, larger than the calyx. Nectary glandular, surrounding the base of the germen. *Stam.* Filaments eight, erect, thread-shaped, longer than the petals; anthers roundish, of two cells. *Pist.* Germen superior, ovate, acute; styles two, somewhat spreading, the length of the stamens, permanent; stigmas obtuse. *Peric.* Capsule elliptic-oblong, with two points, two cells, and two valves, whose inflexed margins form the double partitions. *Seeds* about eight in each cell, roundish.

Eff. Ch. Calyx of four leaves. Petals four. Capsule superior, with two beaks, two cells, and two valves with inflexed margins. *Seeds* several.

A very handsome genus of extra-European shrubs, with opposite, compound or simple leaves, accompanied by interfoliate deciduous stipulas. The flowers are small, copious, racemose, rarely paniced. *Capsules* permanent long after the seeds are shed. CUNONIA, (see that article,) appears to differ from this genus, merely by adding one-fifth to the parts of fructification, which in this case is of no avail whatever.

Sect. 1. *Leaves compound.*

1. *W. glabra.* Smooth Pinnate *Weinmannia*. Linn. Suppl. 228. Willd. n. 1. Swartz Obf. 151. (*W. pinnata*; Linn. Sp. Pl. 515, excluding the reference to Browne.)—Leaves pinnate; leaflets obovate, crenate, smooth on both sides. Capsule roundish-elliptical, bluntish.—Native of the West Indies. The stem, usually shrubby, sometimes becomes a tree, forty feet high, with round, rugged branches; when young angular, and coarsely downy. *Leaves* of six pair, more or less, with an odd one, of obovate, abrupt leaflets, half an inch at most in length, all nearly equal, furnished with one rib and several transverse veins; entire and wedge-shaped towards the base. *Common footstalk* jointed,

each articulation, between the leaflets, winged with a leafy rhomboid expansion, tapering most downward, and hairy at each end. *Clusters* opposite, at the end of each branch, on hairy axillary stalks, dense, about an inch long when in flower; twice as long, and much more lax, when in fruit. *Flowers* very small, white, on fasciculated, short, thick, hairy partial stalks. *Capsules* about half the size of hempseed, brown; their stalks elongated; their valves obtuse, tipped with the styles, and, as they ripen, turning their pale narrow edges, which had formed the partitions, outwards. Permanent styles mostly recurved, rather shorter than the valves. We have not seen the seeds.

2. *W. tinctoria.* Red-tan *Weinmannia*. (*Weinmannia*; Lamarck t. 313. f. 1. Tan-rouge; Commerçon MSS.)—Leaves pinnate; leaflets elliptical, crenate, smooth on both sides. Capsule ovato-lanceolate, taper-pointed. *Seeds* hairy.—Gathered by Commerçon in the isle of Bourbon, where it is known by the name of *Tan-rouge*, because the bark serves to dye leather of a red colour. The flowers are supposed to furnish the bees with much of their honey. French botanists appear to have confounded this plant with the preceding. It is certainly what Lamarck has figured, and what Poir. has quoted, for *W. glabra*, the latter having taken *Tan-rouge* from hence, for his French generic name of the whole genus, though without adverting to its use in the isle of Bourbon, or its being a native of that country. The leaves are full twice the size of *W. glabra*, with elliptical, not obovate, leaflets: wings of their footstalks similar to the last. *Clusters* of flowers much more lax, and less hairy, three or four inches long; the flowers twice as large. *Capsules* of a very different shape, and paler redder hue, tapering into the straight erect styles, which are not a quarter so long as the valves, nor are the edges of the latter ever turned outward, or flattened. The clusters of ripe capsules are cylindrical, dense, four or five inches in length. *Seeds* clothed with a few long prominent hairs.

3. *W. hirta.* Hairy-leaved *Weinmannia*, or Bastard Braffetto. Swartz Ind. Occ. 691. Willd. n. 2. Poir. in Lam. n. 3.—Leaves pinnate; leaflets elliptic-ovate, crenate, hairy at the back. Capsules oblong.—Native of lofty mountains in the south part of Jamaica, in St. Andrew's parish, near Coldspring, the residence of Matthew Wallen, esq. (See WALLEIA.) This, according to Dr. Swartz, from whom we have a specimen, is a very rare species. It is either a shrub, or a handsome tree, from forty to fifty feet high, crowned at the very top of its smooth trunk with lax, hairy, or somewhat downy, rusty-coloured branches. The leaves most resemble the last in shape, but are clothed beneath, sometimes on both sides, with coarse, scattered, prominent hairs. The leafy borders of each joint of the common footstalk are narrower, and less angular, than those of our first or second species, and their midrib is very hairy beneath. *Clusters* also very hairy, an inch or two in length, in pairs at the summits of the branches. *Flowers* the size of the last, white. *Capsule*, according to Swartz, small, oblong, rather pointed, with several small roundish seeds. This tree flowers in September and October. Some specimens, in the herbarium of the younger Linnæus, excite a doubt whether the hairiness of the foliage may invariably be relied on. Still we have no doubt of the distinctness of these three species. The third is perhaps most allied to the second, which appears to be what Dr. Swartz saw marked *W. arborea*, and which Commerçon was said to have gathered in the isle of Mauritius. We do not at all comprehend how the joints of the common footstalk can be termed "somewhat heart-shaped," in *W. hirta*; they are rather more truly obo-

vate than in either of the foregoing, being less angular, or deltoid.

4. *W. trichosperma*. Hairy-seeded Weinmannia. Cavan. Ic. v. 6. 45. t. 567. Poiret n. 2.—Leaves pinnate; leaflets elliptic-oblong, serrated, smooth on both sides. Capsule roundish-elliptical. Seeds densely hairy.—Gathered by Louis Née, at San Carlos, in Chili, bearing ripe capsules in February. *Cavanilles*. By the plate above quoted, this bears most resemblance to the first species, especially in the acute angles of the deltoid articulations of the *footstalks*, which in all the other species are rounded. But the *leaflets* are longer and more elliptical, serrated rather than crenate; the *capsules* broadly elliptical, not obtuse, their inflexed edges, if the figure be accurate, much broader, and continuing inflexed. The *seeds* are roundish-kidney-shaped, clothed with long, copious, projecting hairs, of which no mention is made by any botanist who has described the *seeds* of *W. glabra* or *W. hirta*, and therefore we must presume they do not exist in those species. We find such hairs, very sparingly, on the globular *seeds* of *W. tinctoria*, but the *capsules* of that species are abundantly different from the present.

5. *W. tomentosa*. Woolly Weinmannia. Linn. Suppl. 227. Willd. n. 3. Poiret n. 4.—Leaves pinnate; leaflets elliptical, revolute, entire, woolly beneath.—Gathered in New Granada, by Mutis. A very distinct and remarkable species. The *branches* are woody, round, densely leafy, rough, somewhat warty, of a dark brown; hoary and downy when young. *Leaves* hardly an inch and a half long; leaflets about five pair, with an odd one, each one-third of an inch in length, convex, slightly hairy, single-ribbed; the under side clothed with copious, loose, hoary, woolly hairs. The joints of the common *footstalk* are rather shorter than the leaflets, obovate, not angular; their edges revolute, and the under side woolly. *Stipulas* large, ovate, reflexed, coloured, hairy externally, deciduous. *Flowers* in very dense *clusters*, rather above an inch long, on thick, short, woolly, axillary stalks. *Calyx* hairy. *Capsules* wanting in our specimens.

6. *W. trifoliata*. Three-leaved Weinmannia. Linn. Suppl. 227. Thunb. Prodr. 77. Willd. n. 4. Poiret n. 5. Lamarck f. 2.—Leaves ternate; leaflets obovate, crenate, smooth.—Gathered by Thunberg, at the Cape of Good Hope. The whole *shrub* is said to be very smooth. *Leaflets* equal, about an inch long, being about two-thirds the length of their common *footstalk*, which is simple and naked. *Clusters* cylindrical, dense, two or three inches long, on axillary stalks about half their own length. The *germen* in Lamarck's figure is roundish and hairy. We have seen no specimen, nor is there any account of the *capsule* or *seeds*.

SECT. 2. *Leaves simple*.

7. *W. racemosa*. Smooth-clustered Simple-leaved Weinmannia. Linn. Suppl. 227. Willd. n. 5. Forst. Prodr. 27. Poiret n. 580.—Leaves simple, stalked, ovate, with tooth-like serratures. Clusters axillary, solitary, nearly smooth.—Gathered by Forster, as well as by Menzies, in New Zealand. The *branches* are stout, woody, repeatedly branched in an opposite manner, round and rough. *Footstalks* stout, smooth, half an inch long, articulated at the summit with the leaf, which is two, or two and a half, inches long, and one broad, pointed, coriaceous, quite smooth, strongly veined, beset with blunt, inflexed, wavy teeth, or serratures; paler beneath. *Clusters* about the tops of the branches, though axillary, stalked, longer than the leaves, cylindrical, continuous; their general and partial *stalks* either slightly downy, or quite smooth. *Capsules* obovate, pointed, some-

what downy; the inflexed edges of their valves finally expanded. We cannot find a *seed* in any of our specimens.

8. *W. parviflora*. Small-flowered Weinmannia. Forst. Prodr. 29. Willd. n. 6. Poiret n. 7.—“Leaves, simple, nearly sessile, ovate, pointed, with tooth-like serratures. Clusters terminal, aggregate, hairy.”—Native of Otaheite. *Forster*. Willdenow, who had seen a dried specimen, describes the *branches* as hairy when young. *Leaves* on short stalks, oblong, smooth on both sides. *Clusters* downy, from three to six at the top of each branch, forming a sort of panicle. *Flowers* but a quarter the size of the preceding.

9. *W. ovata*. Ovate-Crenate Weinmannia. Cavan. Ic. v. 6. 45. t. 566. Poiret n. 9.—Leaves simple, elliptical, crenate, acute at each end, on short stalks. Clusters axillary, solitary, opposite, somewhat downy.—Native of Peru, in a large alluvial excavation, near the town of St. Buenaventura, flowering in June and July. This is a *tree* eighteen feet high, with furrowed, rather knotty *branches*, thickened at the insertion of the *leaves*, which seem very like those of *W. racemosa* in shape, size, veins, and smoothness, but are more truly crenate, and stand on shorter *footstalks*. *Clusters* opposite, at the tops of the branches, though axillary and solitary, each two or three inches long; their partial stalks aggregate, and somewhat villous. Nothing is known of the *capsule* or *seeds*. We could wish for better materials than *Cavanilles* affords us, for distinguishing this species from the *racemosa*, n. 7.

10. *W. paniculata*. Panicked Weinmannia. Cavan. Ic. v. 6. 44. t. 565. Poiret n. 8.—Leaves simple, elliptic-lanceolate, sharply serrated. Panicles axillary, compound.—Gathered by Louis Née, at the sea-shore near Talcahuano, in Chili, flowering in February. A *tree* about the stature of the last, but the *leaves* are longer, more lanceolate, with parallel veins, and copious sharp serratures, which give them some resemblance to the sweet-chestnut leaf. They are smooth, and stand on stout downy *footstalks*. The panicked *inflorescence* is singular among all the known species. *Flowers* yellowish-red. *Capsules* elliptical, acute, downy, beaked with the straight *styles*, which are as long as the valves. *Seeds* obovate, smooth, on slender stalks, pendulous. We have a specimen from the late abbé Cavanilles.

WEINSBERG, in *Geography*, a town of Wurtemberg; a part of which is built on a round hill, on which also stands a ruined castle: the other part lies in a valley. In it is a special superintendency. The valley in which it lies is famous for wine; 5 miles N.E. of Heilbronn.

WEINSTEIG, a town of Austria; 8 miles N. of Korn Neuburg.

WEINZIERL, a town of Austria; 8 miles S.E. of Ips.

WEIPERSHOFEN, a town of the principality of Anspach; 5 miles S.E. of Creilshelm.

WEIPERT, a town of Bohemia, in the circle of Saatz; 14 miles W. of Commotau.

WEIR, one of the smaller Orkney islands, containing about 65 inhabitants. It had formerly a church, which is now in ruins; 2 miles S. of Rousa.

WEIR, or WEAR, in *Rural Economy*, a sort of dam, bulwark, or strong erection, formed across a brook, rivulet, stream, river, main, or other such water-course, for the purpose of diverting or turning the water, in watering land. It is occasionally made in different ways, as of timber alone, sometimes of bricks, or stones, and timber, and of different other materials, as will be seen below, having from two to eight or ten thoroughs or openings for letting the water pass through, according as the breadth of the

stream and other circumstances may be. The height of it is always equal to the depth of the stream compared with the adjacent land.

The water of a very small and gentle stream may often be diverted for this use, by means of a few fods firmly put down, with some stones above them: but for lands of any considerable extent, the kinds directed below are necessary, according as the strength of the respective streams may happen to be.

Strong wooden beams or balks thrown across the stream, and made close by means of boards well secured, are, in many cases, sufficiently strong, commodious, and convenient, in slow moving waters, of no great power or force.

A few cart-loads of stones thrown properly in across the stream, forms also a bulwark, wide at the base, and narrowing towards the top, the whole being puddled with clay or gravelly earth, which sometimes answers well. Over the top of this bulwark, the superfluous waters pass in a free manner, falling down the gentle slope, to which, if well constructed, they do no sort of injury.

A weir suitable for a small river may consist too of several rows of stakes, firmly driven down and interlaced with the branches of fir-trees, the intervals of the rows being filled with stones. The sand and mud that come down with the floods fill up this sort of weir, and render it fit for effecting its purpose. In heavy rains the superfluous water passes entirely over.

But for more powerful rivers, the weirs may be constructed of strong frame-works of wood, firmly and strongly joined together, and the different compartments all paved with large stones: the weir rising very gradually against the stream, and being made to slope gradually away before it, as it flows over it. In this way the largest and most powerful rivers may mostly be managed, if the weirs be well suited to them; so that it is but in few cases advisable to attempt the watering lands from rivers that cannot be diverted by one or other of these sorts of weirs, as the expense and hazard taken together may greatly exceed the advantage to be derived: It may, however, in some cases of large rivers, be necessary and proper to have recourse to more expensive weirs, such as that described below.

In this weir, which was formed on a large, rapid, and strong river, under the direction of the Rev. W. H. Coham, in Devonshire, after the stream had been temporarily diverted, and every thing removed for a proper foundation, a double row of pits was dug into a rocky substratum, directly across the bottom, or bed of the river, at about five feet asunder lengthways, by four feet in breadth, and about two feet in depth; and into these pits oak posts of about six or seven inches square were fixed. The mason then raised a perpendicular wall, without any cement, about five feet and a half thick, entirely enclosing the posts, the labourers being employed in the mean time in *backing up* the wall on the higher side with some of the *stiffest* clay to be had. This was, however, afterwards found to be wrong; it should have been done in the *puddle* manner, by means of mould and gravelly earth.

When the wall was raised to such a height as was deemed necessary, in relation to the level required, and the preservation of the lands adjacent, the upper parts of the oak posts were sawn off, in order to receive cross-pieces and joists, the front posts being then left to stand about six inches higher than the hinder ones; and on these joists oak planks were pinned, about six feet and a half long by three inches thick. These planks were brought forward to project about

one foot and a half over the perpendicular of the wall, on the lower side, forming a sort of lip, as it has been termed; the clay, together with these planks, constituting an inclined plane, and terminating at the distance of about fifteen feet up the stream, on the common bed of the river.

The entrance for the *leat* was cut at about thirty feet above the *lip* of the weir, where, to regulate the quantity of water to be admitted, three strong flood-hatches, to be lifted or let down by a lever and windlafs, were placed; and through which a column of water, of about eight feet in width by four feet in depth, may be introduced at any time. Between the leat and the river a stone wall, strongly cemented, is erected, which is about eight feet in height, and carried from the head of the leat to about thirty feet below the weir, in a parallel line with the river, and at the end of which wall another flood-hatch is fixed on a level with the bed of the river. This latter hatch will always be of great advantage when any reparations may be wanting on the weir; as on drawing it up when the water is low, the weir in a few hours will be left perfectly dry, and the workmen, with the greatest convenience, may proceed in their operations. From the top of the side wall, above the weir, the ground is made sloping to the river, and below it is covered with turf, and levelled as a foot-path.

Immediately below the weir, in this case, there is an outlet regulated by another flood-hatch, and conducted through a *shoot* formed of oak plank, from the leat, and contrived for the admission of salmon, which are there sometimes taken; and below the lower flood-hatch, a trap, or *willey*, as it is there termed, is made for the catching of smaller fish: this part of the work does not, however, properly belong to this kind of weir, therefore it need not be more noticed.

The height of the weir is about four feet above the level of the river where it is fixed; and its length, from bank to bank, directly across, or at right angles with the stream, is about forty-eight feet; forty feet of which is carried at a perfect level, and over which the water falls precisely at the same depth, forming a beautiful cascade. The remaining portions of the length of the weir, namely, four feet on each side, are raised, gradually ascending to the banks for the purpose of warding off the torrent from them in time of floods, when the river, in this case, is very tumultuous.

The lip part of the weir is found to answer perfectly; as in proportion to the force of the water behind, so is the distance which it is thrown over the weir from the foundation of the perpendicular wall.

If the writer had not been foiled, and had part of the work to perform over again, in consequence of the use of clay, as already noticed, being under the necessity of driving on the weir in a direct line with the former work, into the side of the opposite bank, as before; and after removing as much of the clay as could be got at, which will not unite completely with the soil, but become liable to be undermined by the water, by making a *puddle*, as used in canals of mould and gravel, in its stead, which succeeded in a complete manner; the whole cost of the weir would not have exceeded 75*l*.

This weir or wear, from its present appearances, may now, it is said, seem to bid defiance to time; and be safely recommended as a pattern to those who may have occasion to construct any thing of a similar kind, either for watering land, for machinery, or other uses. See WATERING Land.

In the weirs or wears which are thrown over large rivers for the purpose of raising the water for the use of mills, and in many other intentions, and which are mostly constructed

of stone, with strong framed wood-work, in somewhat the above manner, there are many different contrivances calculated for different uses, such as locks for securing large fish, places for taking and preserving those of the smaller sorts, and different others. See Dr. Anderson's Treatise on the Erection of Weirs, &c. where a full explanation of the principles and manner of constructing them will be found.

WEIS SEE, in *Geography*, a lake of the duchy of Carinthia; 10 miles N.W. of Velach.

WEISA, a town of Saxony, in the circle of Erzgebirg; 3 miles S.S.W. of Wolkenstein.

WEISBRON. See VESPRIN.

WEISCHE OPPA, a river of Silesia, which runs N.E. into the Schwartz Oppa.

WEISCHENFELD, a town of Bavaria, in the bishopric of Bamberg; 18 miles E.S.E. of Bamberg. N. lat. 49° 49'. E. long. 11° 19'.

WEISDORF, a town of Germany, in the principality of Culmbach; 3 miles E. of Munchberg.

WEISEN, a town of Prussia, in the province of Oberland; 10 miles W.S.W. of Leibstadt.

WEISENBAD, a town of Saxony, in the circle of Erzgebirg; 3 miles S.S.E. of Wolkenstein.

WEISENBERG, a township of Pennsylvania; 60 miles N. of Philadelphia.

WEISENBERG, or WOSSBERK, a town of Lusatia; 8 miles E. of Budissen. N. lat. 51° 12'. E. long. 14° 40'.

WEISENBRUN, a town of Bavaria, in the bishopric of Bamberg; 24 miles S. of Cronach.

WEISENBURG, a town of Austria; 12 miles S.S.W. of St. Polten.

WEISENBURG. See WEISSEMBURG.

WEISENHORN, a town of the duchy of Baden, situated in a county to which it gives name, on the Roth; 11 miles S.E. of Ulm. N. lat. 48° 17'. E. long. 10° 8'.

WEISENKIRCHEN, a town of Austria; 11 miles S.W. of Tulln.

WEISFURT, a river of Silesia, which runs into the Oder, 3 miles below Beuthen.

WEISKIRCH, a town of Bohemia, in the circle of Boleslaw; 3 miles S.S.E. of Krottaw.

WEISKIRCHEN, or HRANITZE, a town of Moravia, in the circle of Prerau; 15 miles E.N.E. of Prerau. N. lat. 49° 30'. E. long. 17° 43'.

WEISMAYN, a town of Bavaria, in the bishopric of Bamberg; 20 miles N.E. of Bamberg. N. lat. 50° 6'. E. long. 11° 18'.

WEISSE, CHRISTIAN-FELIX, in *Biography*, a German poet, was born in 1726, at Annaberg, in Saxony, and educated, first at the Gymnasium of Altenburg, and afterwards at Leipzig. The objects to which his taste most powerfully inclined him were poetry and the drama; and he and his friend Lessing concurred in translating for the stage from French and English works, and afterwards in furnishing original compositions. He also contended with his friend in lyric poetry. After completing his course of education, he became private tutor in a family of distinction at Leipzig, pursuing his dramatic and poetical career, and gaining a great degree of popularity. He also edited the Bibliotheque of Belles Lettres, when Nicholai surrendered it. Although, in 1761, he obtained a place in the revenue at Leipzig, he prosecuted his employment as a writer for the stage; and when he became the father of a family, he directed his attention to education, and published several pieces in this department: particularly, in 1772, a collection of short tales and moral maxims, which had a consider-

able circulation; and in 1775 he revived a weekly publication, which Adelung had discontinued, under the title of the "Children's Friend." This work became afterwards a quarterly publication, and between the years 1775 and 1782, passed through five editions. From this popular work Berquin derived the idea of his "Ami des Enfans," and he was indebted to it for many of his materials. As Weisse's children grew to maturity and settled in the world, he altered the plan of his work, and continued it under the form of Letters; and Berquin also followed him in his "Ami des Adolescents." In 1790 the beautiful estate of Stotteritz near Leipzig, which Weisse inherited, placed his family in affluent circumstances, and furnished him with a pleasant residence. Towards the latter part of his life he contributed short fables and poetical tales to journals and periodical publications, which were well received, and at length closed his life with reputation, in December 1804. His dramatic works, which were continued to five volumes, are said to have formed an epoch in the history of the German stage, and both his translations and original compositions were well received. Gen. Biog.

WEISSE, in *Geography*, a river of Prussia, which runs into the Rufs, 20 miles N.W. of Tilsit.

WEISSEBERG, a mountain of Bohemia, celebrated for the defeat of the elector-palatine, about 3 miles from Prague.

WEISSELBURG, a town of Prussia, in the province of Oberland; 5 miles S. of Marienwerder.

WEISSELMUNDA. See WEICHELSELMUNDE.

WEISSEMBURG, or KORN WEISSEMBURG, or *Weisseburg*, a town of France, and principal place of a district in the department of the Lower Rhine, situated on the Lauter, at the foot of the Vosges. This town was formerly imperial, and was ceded to France by the peace of Ryfwick. The fortifications were destroyed by Louis XIV.; but strong lines of defence are fixed from this town to the Rhine, a little to the east of Lauterburg, on the S. side of the Lauter; 27 miles N. of Strasburg. N. lat. 49° 3'. E. long. 8°.

WEISSEMBURG, a town of Bavaria, called *Weisseburg near the Nordgau*. It contains two churches and a medicinal spring. Weisseburg was an imperial town, till in 1802 it was given to the elector of Bavaria; 28 miles S.S.W. of Nuremberg. N. lat. 48° 58'. E. long. 10° 55'.

WEISSEMBURG, or *Alba Julia*, or *Carlsburg*, or *Fejervar*, a town of Transylvania, capital of a county, and see of the bishop of Transylvania, beautifully situated on the Maros. It was a long time the metropolis of Dacia, and the seat of its monarchs, who had a palace here. It was likewise the seat of a Roman legion. The name Alba Julia it owes to Julia Augusta, mother of Marcus Aurelius. Charles VI. named it Carlsburg; 90 miles N.E. of Temesvar. N. lat. 46° 16'. E. long. 24° 10'.

WEISSEN SEE, a lake of Prussia; 12 miles W. of Lick.—Also, a lake of Bavaria, in the territory of Augsburg; 2 miles S.W. of Fuesfen.—Also, a lake of Carinthia; 6 miles S. of Saxenburg.

WEISSENAU, a princely abbey of Germany, in the circle of Swabia. In 1802 it was given to the elector of Bavaria; 2 miles S. of Ravensburg.

WEISSENBACH, a town of the principality of Culmbach; 5 miles E. of Kirch Lamitz.—Also, a town of Austria; 12 miles N. of Grein.—Also, a town of Austria; 9 miles W. of Freystatt.

WEISSENBERG, a township of Pennsylvania, in the county of Northampton, containing 1046 inhabitants.

WEISSEN-

WEISSENBORN, a town of Saxony, in the circle of Erzgebirg; 3 miles S.S.E. of Freyberg.

WEISSENBURG, a town of Saxony, in the circle of Erzgebirg; 5 miles S.S.W. of Zwickau.—Also, a village of Switzerland, in the canton of Berne, celebrated for its medicinal baths; 18 miles S. of Berne.

WEISSENDORF, a town of Bavaria, in the bishopric of Bamberg; 9 miles S.W. of Forcheim.

WEISSENFELS, a town of the duchy of Carniola; 28 miles W.N.W. of Crainburg.—Also, a town of Thuringia, on the Saal. It gives title to a branch of the house of Saxony, called Saxe Weissenfels, who ordinarily reside in a citadel above the town, called Augustusberg; 18 miles W.S.W. of Leipzig. N. lat. $51^{\circ} 14'$. E. long. $11^{\circ} 59'$.

WEISSENHORN, a town and citadel of Bavaria, which gives name to a county belonging to the lords of Fugger; 8 miles S.E. of Ulm.

WEISSENKIRCH, a town of Bavaria, in the principality of Aichtatt; 3 miles S.S.E. of Aichtatt.

WEISENPACH, a town of Austria; 4 miles N.W. of Bohmisch Waidhoven.

WEISSENSEE, a town of Thuringia, near what formerly constituted an inland lake, which was divided into the Great and Less, or into the Upper and Lower, between both which it lay; but the former being drained in the year 1705, and converted into arable and meadow grounds, a small part of it only being then left; and this also has been since dried up; 14 miles N. of Erfurt. N. lat. $51^{\circ} 10'$. E. long. $11^{\circ} 6'$.

WEISSENSTADT, a town of Germany, in the principality of Bayreuth, on the Egra, where it forms a large pond or lake, abounding in fish; 6 miles N.N.W. of Wunsiedel.

WEISSENTHURN, a town of Slavonia; 18 miles N.N.W. of Verovitza.—Also, a town of the duchy of Stiria; 3 miles E.S.E. of Judenburg.

WEISSESTEIN, a town and castle of Bavaria; 10 miles N.N.E. of Deckendorf.

WEISSIA, in *Botany*, an Hedwigian genus of Mosses, is now, by nearly universal consent, united to GRIMMIA, for reasons given under that article. There is indeed no difference of habit, nor any certain character, however minute and obscure, between them. This is the more to be regretted, as we have few more meritorious claimants for distinction in cryptogamic botany than Mr. Frederic William Weis, author of the *Plante Cryptogamice Florae Gottingensis*, an octavo volume, printed at Gottingen, in 1770. No student in that department of the science can dispense with this little book, in which the synonyms of the descriptions are treated with equal practical skill. *Fungi*, and necessarily Sea-weeds, are excluded from this *Flora*. We trust some responsible author will restore a *Weissia*, worthy of bearing the name. The double *fs* is a blunder which requires correction.

WEISSLAREUT, in *Geography*, a town of Germany, in the principality of Culmbach; 4 miles S. of Hof.

WEISSNITZ, or WEISSERITZ, a river of Saxony, which rises in two branches, the Wilde and Rothe, which unite two miles E. of Tharand, and afterwards run into the Elbe, near Dresden.

WEISTHURN, a town of Bohemia, in the circle of Koniggratz; 6 miles W. of Schlan.

WEISTRA, a town of Austria; 5 miles E. of Steyr.

WEISTRITZ, a town of Silesia, in the principality of Schweidnitz, on a river of the same name. Gold is found in the environs; 2 miles S. of Schweidnitz.

WEISTRITZ, a river of Silesia, which runs into the Oder, near Schweidnitz.

WEISWASSER, a town of Bohemia, in the circle of Boleflaw; 6 miles N.W. of Jung Buntzel.—Also, a town of Silesia, in the principality of Neisse; 4 miles S.W. of Patfchkau.

WEISZBACH, a town of Saxony, in the circle of Erzgebirg; 5 miles N.N.W. of Wolkenstein.

WEITENFELDS, a town of the duchy of Carinthia; 2 miles W.S.W. of Gurck.

WEITENHAGEN, a town of Anterior Pomerania; 2 miles S.S.W. of Griefswalde.

WEITENSTEIN, a town of the duchy of Stiria; 8 miles S.E. of Windfisch Gratz.

WEITRA, or WEITRACH, a town of Austria; 36 miles N.W. of Crems. N. lat. $48^{\circ} 41'$. E. long. $14^{\circ} 59'$.

WEITRASILD, a town of Austria; 2 miles S. of Hardegg.

WEITTENEG, a town of Austria, on the Danube; 18 miles above Crems.

WEITZ, a town of the duchy of Stiria; 11 miles N.E. of Gratz.

WEITZSBERG, a mountain of Stiria; 10 miles N.E. of Gratz.

WEIXEN, a river of Austria, which runs into the Danube, 3 miles below Grein.

WEIZLPACH, a town of Austria; 12 miles W.S.W. of St. Polten.

WEKLSDORF, a town of Bohemia, in the circle of Koniggratz; 7 miles N.W. of Branau.

WELACH. See VELACH.

WELANG, a small island in the East Indian sea. S. lat. $1^{\circ} 25'$. E. long. $130^{\circ} 30'$.

WELAU, a town of Prussia, in the province of Samland; 28 miles E.S.E. of Königsberg. N. lat. $54^{\circ} 36'$. E. long. $21^{\circ} 23'$.

WELCH MOUNTAINS, mountains of Pennsylvania; 30 miles W. of Philadelphia.

WELCHEIM, a town of Bavaria; 7 miles N.W. of Neuburg.

WELCKERSHAUSEN, a town of Germany, in the county of Henneberg; 3 miles N. of Meinungen.

WELCOME BAY, a bay on the west end of the island of Java. S. lat. $6^{\circ} 35'$. E. long. $105^{\circ} 30'$.

WELD, or WOLD, *refeda luteola* of Linnæus, a plant used by the dyers to give a yellow colour; and for this reason called, in Latin, *luteola*, of *luteus*, yellow. For the characters, see RESEDA.

When the plants are pulled, they may be set up in small handfuls to dry in the field, and when dry enough, tied up in bundles and housed dry; care being taken to house them loosely, that the air may pass between them to prevent their fermenting. That which is left for seeds should be pulled as soon as the seeds are ripe, and set up to dry, and then beat out for use; for if the plants are left too long, the seeds will scatter. Mortimer and Miller.

Weld is much cultivated in Kent, for the use of the London dyers.

Mr. Hellot observes, in his Art de Teindre, that for dyeing with weld, the best proportions of alum and tartar for the preparatory liquor are four parts of alum, and one of tartar, to sixteen of the wool; the quantity of the tartar being determined by the greater or less brightness of colour proposed; and that the wool, thus prepared, is to be boiled again with three or four parts of weld to one of wool, but often much less: that for light shades, it is customary to diminish the alum, and omit the tartar; and that, in this case,

case, the colour is more slowly imbibed, and proves less durable.

With a view to economy, the weaker shades of colour are dyed in the same bath, after the stronger are finished. A golden yellow, more or less orange, is given by a weak madder bath, after the welding.

Silk is dyed of a golden-yellow, generally with weld alone, according to the following process: the stuff is first boiled in soap-water, alumed and washed, then passed twice through a weld bath, in which, the second time, some alkali is dissolved, which gives a rich golden hue to the natural yellow of the weld. The colour is further deepened by a little annotto. The solutions of lime with weld give to silk a bright clear yellow. In order to dye cotton yellow, Berthollet directs first to cleanse it with wood ashes and water, to rinse, alum, and dry without further rinsing, and then to pass it through a yellow bath, in which the weld is somewhat more than the weight of the cotton. When the colour has sufficiently taken, the cotton is thrown into a bath of sulphate of copper and water, and kept there for an hour; after which it is boiled with white soap-water, and, lastly, washed and dried. In order to obtain a deeper jonquil-yellow, the aluming is omitted, and, instead of this operation, a little verdigris is added to the weld bath, and the cotton finished with soda.

Weld is particularly preferred to all other substances in giving the lively green lemon-yellow. It is, however, expensive; and it is also found to degrade and interfere with madder colours more than other yellows. We may here add, that the fine delicate yellow, obtained from weld, is much used by the London paper-stainers, and sold in the form of hard lumps, consisting chiefly of chalk saturated with the colouring matter. Messrs. Collard and Frazer have given the following improved process:—Dissolve any quantity of fine whiting in boiling water; add to it one ounce of alum for every pound of whiting, which will occasion a brisk effervescence, and stir these materials well together till the gas is wholly disengaged. On the other hand, boil in a separate vessel some weld with water just sufficient to cover it, for fifteen minutes, filter the yellow decoction, and then mix it with the whiting and alumine in such proportions, that the earths may appear to be saturated with the colouring matter. Then let the mixture remain a day at rest, and at the bottom will be the precipitated earth firmly united with the colour, and of a fine yellow tinge, which may be conveniently dried on chalk-stones.

The weld yellow is a water colour, and is never mixed with oil.

WELD, in *Agriculture*, is a plant which is not unfrequently cultivated in the field by the farmer as a crop, for the purpose of giving and affording a bright yellow and lemon colour to woollens, silks, cotton, and thread, as well as for its use in the manufacture of check and fustian, and in some other intentions. It is for the flower-stems that it is principally grown, as being useful in the process of dyeing these several articles. It is often known by the names of *woold* and *dyer's weed*.

It may be noticed, that in the growth and culture of this plant, the soils most suitable are those of the fertile mellow kinds, whether of the loamy, sandy, or gravelly sorts; but it may be grown with success on such as are of a poorer quality; but in the former, the plants will rise to a much greater height, and produce much larger leaves and stems, than in the latter description of lands.

It has, however, been stated, that the soil most suitable to it, in *Essex*, is the strong stiff loam moderately moist,

but not wet. A soil rather moist, but mellow, seems the most suitable and proper for it.

It is necessary, in the preparation of the ground, that there should be a tolerable degree of fineness produced in the mould of the soil, which may be effected by repeated ploughings given in the more early spring months, and suitable harrowings. The surface of the land in the feed furrow should be left as level as possible, that the seed may be dispersed more evenly over it, and with greater regularity and exactness.

In this, as in many or indeed most other cases, the seed should be collected from the best plants, and those which have remained upon the stems till rendered perfectly ripe; as such only vegetates perfectly, and the plants in such cases should not be left stand too long, as the seed is liable to shed. It should be perfectly fresh when used, as old seed never comes up well, or in so regular a manner.

In regard to the proportion of seed which is necessary, it is commonly from about two quarts to a gallon the acre, according to circumstances, when sown alone: but when mixed with other crops, a little more may be required, which should be blended with a little sand, or some other such material, at the time of sowing it on the land, as rendering it capable of being sown more evenly.

It may be observed in respect to the time of sowing, that this sort of crop may be put into the ground either in the spring, as about the latter end of April or beginning of May; or in the latter end of summer, as the beginning of August; being mostly sown in conjunction with other crops in the first period; but when sown alone at the latter season, the produce is in general the best and most full. Some of the writers in the *Essex Report on Agriculture* speak of the culture of this sort of crop as simply that of transplanting from the feed-beds about Midsummer. The seed, in these cases, is sown in the beds in the early spring, for raising the plants. In the county of Norfolk, it is said, that they sow it in the month of April with barley, in the proportion of from a quarter to half a peck to the acre, in the manner of clover, and frequently with clover at the same time, to be mown or fed in the following year, after the weld is pulled.

It is mostly sown broad-cast, whether grown in mixture with other plants or alone; and as the seeds are of a very small size, it requires an expert seedsmen to perform the business with regularity and exactness, which is a matter of much importance to the success of the crop, as, where the plants stand too closely together, much unnecessary trouble and expence must be incurred in the thinning them out by the hoe afterwards; and where they stand too thinly upon the ground, there must be a great loss from the deficiency of plants. That the sowing may be executed with more regularity, it is the custom with some to blend other substances, such as the above, with the seed that has nearly the same weight, as by this means they suppose it may be effected with greater exactness, facility, and readiness.

It is stated that weld, when grown with other sorts of crops, such as barley, buck-wheat, beans, peas, clover, or grass-seeds, is usually put in after them; in some cases immediately, but in others not till some time has elapsed. With the first and second sorts, when sown so late as the beginning of May, it is mostly the practice to sow it directly afterwards, giving the land a slight harrowing with a very light close-tined harrow to cover it in. The barley being sown under furrow, the weld-feed with some is immediately sown over the surface, and lightly harrowed in, and then rolled. Where the barley seeding is performed so early as

March,

March, or the beginning of April, the sowing of the weld-feed is best deferred till May, when it may be dispersed over the land, and left in that manner to be washed in by the rains. With bean and pea crops, it is often sown before the last breaking or hoeing of the crops in the latter end of June, or beginning of July. In cultivating it with clover and grass-seeds, it is often sown at the same time with them; but a better practice is, perhaps, to delay it till some time afterwards, as both these crops require to be sown at too early a period for this plant to rise safely. But in cases where no other sort of crop is grown with weld, which is probably the best method, it is usually sown evenly over the surface of the land, and covered in by harrowing with a light bush harrow, having afterwards recourse to the roller in light sorts of land.

Though it is common in cultivating crops of this sort, not to pay any attention to them after being sown; yet as the plants are of slow growth, and liable to be greatly injured in their progress by the rising of weeds, it must be of much benefit not only to keep them perfectly clean, but also to have the mould stirred about their roots. In about a month from the time of sowing, the plants are mostly in a state to be easily distinguished; a hoeing should be then given when the weather is dry, which may be performed in the same manner as for turnips only, using somewhat smaller hoes for the purpose. Some direct that the plants in this operation should be set out to the distance of three or four inches; but it is better to let them have more room, as six, seven, or eight inches; which not only lessens the expence of the business, but contributes to the advantage of the crop. In the spring, a second slight hoeing may be practised about March, in a dry time; and if any weeds rise afterwards, a third may be given in May. Where the land has been well prepared, one hoeing in autumn and another in the spring may be fully sufficient. Hand-weeding, though practised by some, is in general too expensive in these cases.

It may be observed, that the proper period for pulling this sort of crop is when the bloom has been produced the whole length of the stems, and the plants are just beginning to turn of a light or yellowish colour, as in the beginning or middle of July in the second year. The plants are usually from one to two feet and a half in height. It is thought by some advantageous to pull it rather early, without waiting for the ripening of the seeds, as by this means there will not only be the greatest proportion of dye, but the land will be left at liberty for the reception of a crop of wheat or turnips; but in this case, a small part must be left solely for the purpose of providing seed. In the execution of the work, the plants are drawn up by the roots in small handfuls, and set up to dry, after each handful has been tied up by one of the stalks, in the number of four together in a sort of erect position against each other, as is done in some other kinds of crops.

It is remarked, that sometimes they, however, become sufficiently dry by turning, without being set up. After they have remained till fully dry, which is mostly effected in the course of a week or two, they are bound up into larger bundles, that contain each sixty handfuls, and which are of the weight of fifty-six pounds each; sixty of these bundles constituting a load. These last are tied up by a string made for the purpose, and fold under the title of woold cord, in many places where this kind of crop is much grown and provided for the dyer and calico-printer.

On account of the weld plant being extremely uncertain in its growth, and the whole crop seldom becoming in a state

to be pulled at the same time, it is proper to have an experienced labourer to direct the business of pulling, in order that the pullers may not proceed at random, but take the different parts as the plants become ready, or in danger from the blight. In which last case, the greatest possible dispatch should be made, as the loss of weight in the produce will daily increase, and the grower be of course greatly injured in the quantity of it.

After the weld is become sufficiently dried, which is known by the crispness of the leaves, and the stems turning of a light colour, and when the plants are ripe, the seeds shelling out; according to some, it should be stacked up lightly in the barn, in order to prevent its taking on too much heat; while others advise, that it should be stacked up closely in the manner of wheat, being left to sweat in the same way as hay, as the more this takes place, the better; the quality of the weld being thereby increased, if there be no mouldiness. When the crop has stood till fully ripened, the feed may be taken before it is put into the barn, which may be easily procured by rubbing, or slightly beating each of the little handfuls against each other over a cloth, tub, or any other convenient receptacle, as, by threshing, the quantity of the weld would be much reduced in weight. The price of this sort of feed is mostly about ten or twelve shillings the bushel, which may be sold to the seedsmen in a ready manner.

It may be observed, that in crops of this kind the produce is in some degree uncertain, depending much upon the nature of the season; but from half a load to a load and a half is the quantity most commonly afforded, which is usually sold to the dyers at from five or six to ten or twelve pounds the load, and sometimes considerably more.

This is a sort of crop which is mostly disposed of to the dyers and calico-printers, as well as other manufacturers. The demand for it, however, is sometimes very little; while at other times it is so great, as to raise the price to a very high degree.

Weld is a crop which is particularly liable to be injured by the blight, which probably has induced the growers of it to raise it with those of other kinds, especially of the grass sort; because, where the weld crop does not succeed, a portion of sheep feed may be afforded by the others, for winter and spring use. It is noticed, that the blight frequently comes on so suddenly, that crops which appeared healthy, and in a vigorous state of growth, during the whole of the winter and spring, promising a large produce, are about the month of May attacked by this vegetable disease, so as to be nearly destroyed. It is known to be present by the plants, especially about the lower parts of the stems of them, turning of a yellowish or pale reddish colour, while the upper parts remain green, and seem healthy. When it appears early in the month of May, there is always danger of the crop being destroyed; but when it comes on at a later period, or where the plants from other causes, as the dryness of the season, begin to change colour in the stalks, the only chance is that of having them pulled as expeditiously as the business can be performed, and in the readiest manner possible.

It may be remarked, that it would seem better and more convenient to cultivate this crop alone, or without any mixture of other plants; as, in the former way, it must be much injured and confined in its growth, on account of the closeness and shade produced by the plants of the other crops that surround it. It is the custom, too, when grown with other crops, especially those of the grass kinds, to very commonly feed them down in the winter and spring seasons with

with sheep, or some other light sort of live-stock, under the notion that they will not touch the weld plants; but this is by no means the case, as they are found to feed upon them without any nicety, and must, of course, do very great injury to their growth and flowering. In cases where weld is sown among clover, as is not frequently the case, the best method is probably to pull it out when it has got to maturity, before the clover is cut. Where sown on summer fallowed land with rape and grass-seeds, towards the latter end of that season, in which case it often does extremely well, the crops are mostly fed by lambs in the course of a month or six weeks after the sowing, when little or no injury can be sustained by the cropping of the weld plants.

Weld, on account of the great consumption of vegetable food which it causes, without contributing any thing to the amelioration of the land, can only be introduced with propriety, probably, in situations where manure or substances of that kind can be easily obtained. However, in cases where the crops of this kind are cultivated with sufficient tillage, care, and attention, they may be a good preparation for wheat or turnips, in some instances.

It may sometimes, too, be grown with advantage in the neighbourhoods of large dyeing, printing, and other such manufactories, where the consumption, and consequently the demand for it, are very great. If this sort of produce cannot be disposed of soon after it is pulled and tied up, it may be preserved perfectly found for several years, by being stacked either in the barn or on stands in the open air, taking care to prevent the attacks and ravages of rats, or other vermin.

WELD, or *Weald*, in a *Chorographical Sense*. See WEALD.

WELDEREN, or MARIENBURG, in *Geography*, a town of Germany, in the bishopric of Munster; 3 miles N.E. of Dulman.

WELDING, in the *Manufactures*, denotes the forging of iron, when intensely heated; or, more generally, the intimate union which subsists between the two surfaces of two pieces of malleable metal, when heated almost to fusion, and hammered. This union is so strong, that when two bars of metal are properly welded, the place of junction is as strong relatively to its thickness as any other part of the bar. Welding heat is the heat necessary for producing this effect. Bar-iron cannot be welded to another piece of iron, unless both be heated to nearly 60° of Wedgwood's pyrometer, which is equal to 8.877 of Fahrenheit's scale, and is called the welding heat; but if cast-steel be heated to this point, it would be fused, and run down under the hammer; and, therefore, it was for a long time thought to be impossible to use it in conjunction with iron, in the same manner as the other kinds of steel are employed. But sir Thomas Frankland at length discovered, that if the cast-steel be made only of a white heat, and the iron of a welding heat, the steel will then be soft enough to unite with the iron, and yet the former will not become fluid by the operation. It will, however, be proper to give the necessary temperatures to the two metals separately, and then to unite them at one single heat. (Phil. Transf. for 1795, p. 296.) Mr. Parkes observes, that some nicety is required in the process of welding iron, so that the outside of the weld does not oxidize too much and fly off in scales, before the inside is brought up to a welding heat. When, therefore, a skilful workman is about to weld two pieces of iron, he carefully observes the progress of the heat; and if one becomes too hot, he rolls it in sand to preserve it from the action of the atmosphere; and when one piece acquires the necessary temperature before the other, he covers that with sand,

whilst he is bringing the corresponding piece up to a sufficient heat for its uniting properly with the former. Silica, when mixed with the oxyd of iron, forms a very fusible compound, which covers the work under operation, and prevents a further oxidation of the metal. Iron and platina are capable of a firm union by welding. See sir John Hall's Experiments, in vol. vi. of Edinb. Phil. Transf. p. 71. Parkes's Essays, vol. iv.

WELDING, the proper heat smiths give their iron in the forge, in order to double up the same, when wanted to weld a work in the doublings, so as to be in one piece thick enough for the purpose it is wanted for.

WELDING-Heat is the strong heat, when the iron is prepared to bind.

WELDON, GREAT, in *Geography*, a small market-town in the hundred of Corby, and county of Northampton, England, is situated in Rockingham forest, 4 miles E.S.E. from the town of Rockingham, and 84 miles N.N.W. from London. A weekly market is held on Wednesdays, but on a small scale; and here are four annual fairs. The market-house, over which are the sessions-chambers, supported by columns, was built by lord viscount Hatton. The parish is famous for its quarries of rag-stone, which takes a high polish, and is in great esteem for chimney-pieces, slabs, &c. In the vicinity of this place were discovered, in the year 1738, some fragments of Roman tessellated pavements, one of which was ninety-six feet long, and ten broad. Connected with this were the floors of seven rooms; the centre one, being the largest, was terminated at one end with five sides of an octangular projection. Among the ruins were found several Roman coins of the lower empire. A wall has been built round the Roman pavement, and a wooden roof placed over it. Near Great Weldon, and forming part of the parish, is Little Weldon, a village so called in reference to the town, though exceeding it in population. The whole parish, according to the return to parliament in the year 1811, contained 166 houses, and 815 inhabitants.—*Beauties of England and Wales*, vol. xi. Northamptonshire, by Rev. J. Evans, and J. Britton, F.S.A., 1810.

WELDS, a river of America, which runs into the Connecticut, in the state of Vermont.

WELEDIA, a town of Egypt, on the left bank of the Nile; 5 miles N. of Siut.

WELFORD, a town of England, in Northamptonshire, with 931 inhabitants, including 683 employed in manufactures; 15 miles N.W. of Northampton.

WELHARTITZ, a town of Bohemia, in the circle of Prachatitz; 8 miles N.W. of Schuttenhofen.

WELIN, a town of Bohemia, in the circle of Chrudim; 12 miles N.E. of Chrudim.

WELITZEN, a town of Prussia, in the province of Natangen; 5 miles S.S.E. of Marggrabown.

WELKI, a town of Bohemia, in the circle of Kaurzim; 7 miles N.E. of Prague.

WELL, a town of Hindoostan, in Vissiapour; 12 miles E.S.E. of Raibaug.—Also, a town on the north coast of the island of Sumatra. N. lat. 4° 40'. E. long. 97° 20'.

WELL, a hole dug under ground, below the level or surface of the water collected in the strata.

It is usually of a cylindrical figure, and commonly walled with stone, and lined with mortar.

In sinking wells, it is a consideration of some importance, that they should be lined with free-stone, and not, as is usually the case, with bricks; because most of the bricks which are made in this country, have the property of hardening the water; but the stone does not produce this effect.

M. Blondel informs the Royal Academy of Sciences of a device they use, in the Lower Aultria, which is encompassed with the mountains of Stiria, to fill their wells with water; *viz.* that they dig in the earth, to the depth of twenty or twenty-five feet, till they come to a clammy earth, which they bore into, continuing the operation till the water breaks forcibly out; which water, in all probability, comes from the neighbouring mountains, in subterraneous channels. Caffini observes, that in many places of Modena and Bologna, they make themselves wells by the same artifice. Dr. Derham adds, that the like has been sometimes found in England, particularly in Essex.

In the Philosophical Transactions we are informed, by Mr. Norwood, that, in Bermudas, wells of fresh water are dug within twenty yards of the sea, and even less, which rise and fall with the tides, as the sea itself does. He adds, that, in digging wells in that island, they dig till they come almost to a level with the surface of the sea; and then they certainly find either fresh water, or salt: if it prove fresh, yet, by digging two or three feet deeper, they always come at salt water. If it be sandy ground, they usually find fresh water; but if hard lime-stone rock, the water is commonly salt, or brackish.

Lay-well, near Torbay, ebbs and flows very often every hour; though somewhat oftener in winter than in summer. Dr. Oliver observes, its flux and reflux sometimes return every minute; though, at other times, not above twenty-six or twenty-eight times in an hour. Philos. Transf. No. 104.

In Scotland they have a well, which Sibbald has mentioned as foretelling storms. It is a deep and large well near Edinburgh, and from the noises heard in it at certain times is called by the people the *routing well*. They go to this to listen after the prefaces of weather, and it is said that storms are particularly foretold by it; and that noises are not only heard in it before storms happen, but that they are always heard determinately and distinctly on that side whence the storm will come.

In the Philosophical Transactions we have an account of a boiling-well, &c. See SPRING.

WELL, in *Rural Economy*, a deep circular opening, pit, or sort of shaft, sunk by digging down through the different strata or beds of earthy and other materials of the soil, so as to form an excavation for the purpose of containing the water of some spring or internal reservoir by which it may be supplied, for domestic or other uses of different kinds.

It is usual to have wells bricked round from the bottom to the top, and frequently to have pumps fixed in them. The width is mostly from three to four feet, which, where the springs are strong, may afford and contain a sufficient quantity of water.

As wells are supplied from springs, and these are formed in the bowels of the earth, by water percolating through the upper strata, and descending downwards until it meets with a stratum of clay or other impervious material that intercepts it in its course, it may naturally be concluded, that an abundant spring for this use need never be expected in any district or place that is covered to a great depth with sand, without any stratum of clay to force it upwards, as is the case in the sandy deserts of Arabia, and the immeasurable plains of Lybia. Neither are we to expect abundant springs for wells in any soil that consists of an uniform bed of clay from the surface to a great depth; for it must always be in some porous stratum that the water flows in abundance, and it can be made to flow horizontally in that only, when it is

supported by a stratum of clay, or other substance that is equally impermeable by water. By this means is explained the *rationale* of that rule so universally established in digging for wells, that if begun with sand, gravel, or other such matters, it need seldom be hoped to find water until clay is come to; and that if clay be begun with, none can be hoped for in abundance till sand, gravel, or porous rock is met with.

Hence, as the doctrine of wells is so much and so intimately connected with the nature of the strata and the springs afforded by them, it may not be unnecessary to observe, that in cases where differently formed strata of sand, to a considerable depth, rest upon beds of clay, and have a free issue at the lowest ends of them, if wells were sunk into the sand-beds higher up no water could be there permanently found until they penetrated quite through the strata of sand, and went to some depth into the beds of clay that lie below them. In such cases, the water could never rise in the wells much higher than a certain point; because, whenever it rose as high as the porous sand, it would flow along through it until it made its escape below; and if the beds of clay should extend backwards under the ground a great way, and at a great depth below the surface, so as to form an abundant and never-ceasing stream under the beds of sand, it must necessarily follow, that the wells will continue constantly at the same height, exactly as in the case of a strong basin at a fountain, into which a pipe of water constantly flows, so as to keep it running over.

If, however, the streams that run below the beds of sand be small, and the draught of water from the wells, at particular times, be uncommonly large, the surface of the water in the wells will of course be made to sink: they may be, indeed, quite drained of water at times, so as to require to be left for a while till they shall fill again. This may be occasionally a very serious inconvenience, and ought to be guarded against by enlarging the reservoir, which may be effected either by widening the diameter of the wells, or by sinking them to a greater depth in the clay, or by both these means. Hence it appears, it is said, that in cases of this sort, very wide wells ought always to be made. Other cases, however, will come to be noticed in the course of this article, in which the straightest well that can be made, would supply a quantity of water as abundant as those that are wider. In these cases, pipes as above will be found very useful.

Nor would the phenomena here described, it is said, be in the least varied if the wells, instead of being dug in the sand immediately below the vegetable mould, should be first sunk through a considerable thickness of some other strata. The depth of the well only would be greater, and all other circumstances the same.

It may be here noticed, that quicksand, when it comes in the way of well-digging, affords impediments which can only be surmounted with great labour and difficulty. The best and most obvious remedy in such cases when they occur, is probably to endeavour to find the means of opening an outlet by which the water may be suffered to run off or discharge itself. This, where the quicksand is situated above the level of the sea, or some adjoining plain, may in many cases be effected at very little expence, if due attention be bestowed upon the position and natural dip of the strata, which may be discovered by various means besides boring. But there are cases, particularly where the quicksand is produced by a cavity like a basin scooped out of the entire bottom, so as to contain water to a considerable depth, which in some particular situations may be deemed incurable.

It deserves also to be remarked, as a circumstance necessarily

cessarily accompanying springs of this kind, that the digging wells in a higher position, will not sensibly diminish the quantity of water that flows over the lower surface of the clay; for, as the well, as soon as it is filled, must overflow, that will not intercept one drop more water than what is drawn up out of it. Were it even possible to pump the water from the well as fast as it falls into it, so as never to allow one drop to run over, the case would not be much altered, because no more water could be thus intercepted than that which would have flowed into the mouth of the well in its descent; so that every drop that would pass the mouth of the well, on either side, would flow forward to the lower situation, as if no well had ever been made. Hence we see that springs of this sort can never be intercepted by wells, or sensibly affected by other wells placed either higher or lower than them. Wherever this cause exists, water will be found nearly in equal abundance, whatever the relative situation of the well may be in respect to others: nothing but an uninterrupted trench, of a size sufficient to intercept all the water as it flowed, and to carry it off, could dry up the springs or wells below it.

It may also be observed, that if the bed of sand be of great extent, if it be at last supported by a bed of clay or other impervious matter, water will undoubtedly be there found, whatever may be the depth of the bed of sand above it, if a well be dug through it; for, as the water that falls in showers upon the earth's surface necessarily sinks through that pervious stratum, it is soon beyond the reach of the sun, so as not to be evaporated, and must sink downwards till it meets with an impervious stratum, so that there can be no doubt but that under the immeasurable deserts of Lybia, there must be water in abundance to supply any number of persons, were wells there sunk to the requisite depth; nor is that depth, perhaps, in many cases, nearly so great as has been in general apprehended.

There are many other cases of strata and springs, as concerned in the opening and forming of wells, that constitute different classes of springs for this use, as those where the water is confined and pent up in retentive beds, so as to be capable of supplying wells by simply boring down into them, or making slight openings in other ways, by which the water may flow up. Some instances of these and other sorts will be noticed and considered below.

In the execution of the work of digging wells, there is no great difficulty, the person employed in the business chiefly working down by means of a small short-handled spade and a small implement of the pick-axe kind; the earthy materials being drawn up in buckets by the hand or a windlass fixed over the opening for the purpose. Where persons conversant with this sort of business are employed, they usually manage the whole of the work, bricking round the sides with great facility and readiness; but in other cases, it will be necessary to have a bricklayer to execute this part of the business. As the expence and trouble of digging and getting up the materials in these cases are considerable, other means have been had recourse to, in order to lessen or prevent them. The most ingenious of these is that proposed by a French philosopher, who has advised that the ground should be perforated to a sufficient depth by means of an auger, or borer: a cylindrical wooden pipe being then placed in the hole and driven downward with a mallet, and the boring continued, that the pipe may be forced down to a greater depth, so as to reach the water or spring. In proportion as the borer becomes filled with earth, it should be drawn up and cleared, when by adding fresh portions of pipe, the boring may be carried to much extent under ground, so that water may in most cases be thus reached and

obtained. It is stated that wells made in this manner are superior to those constructed in the common method, not only in point of cheapness, but also by affording a more certain and abundant supply of water, while no accident can possibly happen to the workmen employed. In case the water near the surface should not be of a good quality, the perforation may be continued to a still greater depth, till a purer fluid can be procured; and where wells have become injured or tainted from any circumstance or accident, when previously emptied, and the bottom perforated in a similar manner, so as to reach the lower sheet of water, it will rise in the cylindrical tube in a pure state into the body of the pump fixed for the purpose of bringing it up.

This is certainly an ingenious, ready, and safe method of forming wells; but it requires a large expensive boring auger, and which, if carried to any great depth, would stand in need of an apparatus for being wrought by means of horse-power. Besides, other parts would be necessary, such as punches, chisels, and other such mouth-pieces, for being fixed on occasionally, in order to work through hard strata of many different kinds; and, in some instances, it would be liable to be wholly impeded by the nature of the substances through which it had to get in its passage to the water or spring. In some cases, it may, however, answer in a ready and perfect manner, and be of great use and convenience. There would be much difficulty, too, in driving down the wooden pipes in many cases, especially if to any considerable depth, and great nicety be required in making them so as pretty exactly to fit the aperture formed by the boring auger. And, besides, from their smallness, except they were made from cast-iron, or some other proper metal, they would not by any means be durable, but speedily become leaky and out of order. The best mode would therefore probably be that of having metallic-pipes cast for the purpose, and so formed as to fit exactly upon each other, to any depth that might be necessary in sinking wells.

In some cases and kinds of strata, wells formed in this manner could not, however, answer perfectly, as they require much width or space at the bottom parts, and sometimes to be dug considerably into the impervious bed or matter, as seen above.

It may be necessary and useful to shew the nature of the different beds or layers of materials which are dug or sunk through in forming the openings for wells in different cases, as well as the manner and heights to which the water or springs rise in them under various circumstances. Some cases of wells are stated in the Corrected Report on Agriculture, for the district about the metropolis, that explain these points in a pretty clear manner.

It is noted, that in the year 1791, the present vicar of Northall, then Mr. archdeacon Eaton, agreed with Mr. White, of Putney, to sink a well in the court adjoining to the vicarage. The workmen first dug through a bed of solid blue clay 60 feet in depth, under which was a stratum of rough porous stone about a foot thick. To this succeeded a second stratum of clay, differing a little from the former in colour, 29 feet in depth; then a stratum of fine grey sand, intermixed with extraneous fossils, as oyster-shells, bivalves, &c. This stratum continued for twenty-three feet, and was succeeded by another of clay, of a red or ferruginous colour, less firm in its consistence than that which occurred before, and intermixed now and then with gravel and stones of a considerable size. After digging through this stratum for fifty-one feet, at the depth of one hundred and sixty-four feet from the surface, water was found, which, on the removal of the stone which lay immediately

diately over, the spring burst up with such force, and in such abundance, that the workmen immediately made the signal to be drawn up. Within the first four hours after its discovery, the water rose to the height of eighty feet, in the next twenty-four hours about forty feet more; after which it continued to rise gradually for the next fortnight, till it reached its present level, which is only four feet from the surface of the earth, the depth of the water being now only one hundred and sixty feet.

At Mr. Munday's brewery at Chelsea, a well was dug about the year 1793, to the depth of three hundred and ninety-four feet, within twenty or thirty feet of the edge of the river, mostly through a blue clay or marl. At the depth of near fifty feet, a quantity of loose coal, twelve inches in thickness, was discovered; and a little sand and gravel were found about the same depth. The well-digger usually bored about ten, fifteen, or twenty feet at a time lower than his work, as he went on; and on the last boring, when the rod was about fifteen feet below the bottom of the well, the man felt, as the first signal of water, a rolling motion, something like the gentle motion of a coach passing over pavement. Upon his continuing to bore, the water presently pushed its way by the side of the auger with great force, scarcely allowing him time to withdraw the borer, put that and his other tools into the bucket, and be drawn up to the top of the well. The water soon rose to the height of two hundred feet.

In 1794, a well was sunk at Norland-house, for Mr. Vuliamy, a little on the road towards the town of Uxbridge, to the depth of two hundred and thirty-six feet, and then a hole of five inches and a quarter was bored down, and a copper pipe of the same diameter as the borer, was driven down to the additional depth of twenty-four feet into a stratum of sand filled with water; when a mixture of sand and water instantly rushed upwards through the aperture of the pipe in such abundance, as to rise one hundred and twenty-four feet, that is, one hundred feet in the well part, and twenty-four in the pipe, in the course of eleven minutes, and one hundred and nineteen feet more in one hour and nine minutes; or on the whole it rose two hundred and forty-three feet in one hour and twenty minutes. A found line was then let down, which discovered that sand had rose in such quantity as to fill the well to the height of ninety-six feet. This was under the necessity of being repeatedly dug out, by which the sand was ultimately reduced so considerably as to permit the water to rise through it more and more freely, until it flowed over the top of the well at the rate of forty-six gallons in the minute. There is still, however, a great body of sand in the well, through which the water filters by ascent, which is excellently calculated for freeing it from every sort of impurity. If a greater supply of water at this well were necessary for the valuable purpose of turning machinery of any sort, or for any other such use, it might certainly, it is said, be obtained after the rate of several hundred gallons in the minute, by continuing to clear out the sand until the

obstruction it affords should become of little consequence; but, in this case, the quality of its water is of more importance than the quantity. The water, in this instance, is now had in a very high state of purity, as the originally excellent water, rendered so by flowing in a stratum or body of clear sand, is further purified and improved by filtering by ascent through many feet in thickness of the same material.

Other circumstances have occurred in digging and forming wells in different situations. It is stated in the Rural Essays, that in sinking a well at Sheerness, near the mouth of the river Thames, sometime since, some extraordinary phenomena or appearances occurred, many of which were deemed, by different persons, rather of a wonderful kind. They were these: that first is placed upon a neck of land, very little elevated above the surface of the sea. In digging the well, they passed first through a bed that consisted wholly of sand to the depth of thirty feet, the whole of the water found in which was of a salt taste, when at that depth they discovered a spring of salt-water, which, not being irresistibly abundant, they found themselves enabled to wall out; which being accomplished, they then sunk further, through a bed of clay for some fathoms more. They here found another spring of salt-water, as before; which having walled out in a similar manner, they continued to dig through the same bed of clay, for three hundred feet more; at the bottom of which they found a bed of gravel, from which issued a copious stream of fresh water, which soon filled the well within five feet of the top; at which height nearly it has ever since remained.

Extraordinary as these circumstances may appear, they are perfectly explicable on the principles and appearances which take place in boring and tapping springs. The fresh water, in this case, being confined and pent up at a very great depth in the earth, by impervious beds of materials, when the gravel or porous stratum that contained the water was sunk down into it, was forced up and rose, of course, to the height of the internal source or reservoir from which the water originally came in the distant high ground. If the spring in this instance should afford more water than is taken from the well, it will continue always about the above height; so that the water can only sink in the top of the well, when more is drawn from it than the spring can supply in a given time. See TAPPING Springs.

The springs of salt-water in this case are capable of being explained on the supposition of fissures or openings having been formed by the working of some sort of animal, or other unknown cause, so as to have penetrated the bed of clay, from the edge next the sea to some distance, as far inward, at least, as the opening of the well; through which, of necessity, salt-water would flow into the well as soon as it was opened. See Philosophical Transactions, vol. 74.

Another instance of a somewhat similar kind, though less complicated, as being divested of the circumstance of the salt-water, is mentioned to have taken place at Derby, under the direction of a late eminent physician and philosopher. A well was sunk in that place, which lies in a bottom, surrounded by many different hills; in which, after digging through a bed of clay for some considerable depth, an abundant spring of fresh water was found, which, as in most cases of this nature, rushed up with great impetuosity, and soon filled the well to the top, where it flowed over in a pretty full stream. This was instantly seen, and conceiving that it probably descended through some narrow subterraneous passage, from a height greater than that of the houses of the town, readily imagined that if the sides of the well could be raised to a sufficient height, making them at
the

the same time strong enough to bear the pressure of the water within, it might be conveyed by this means to the highest floors of the houses; which was actually effected to the great convenience and advantage of the family.

The same circumstances might be taken advantage of in many other situations and cases, with equal benefit and convenience in this way, and still more in many others, especially in the turning of machinery.

Even the situation of the metropolis itself is said to afford a strong example in elucidation of the same general principle. It is well known that this is every where built upon a solid bed of clay, that extends to a great depth, and which lies above a large basin of water there confined and pent in, that can in no way be let off or discharged; in consequence of which, it is with certainty known, that water may be found by sinking a well in any place; and that the well-diggers are become so expert, that they can with little difficulty tell, until within a few feet of the depth to which the well must be sunk before water be found. They know, too, that when the water is found, it always rises in the well until it reaches a certain height, where it remains stationary ever after, never rising or falling scarcely more than an inch from its level under any diversity of season: and if the workmen be permitted to take their levels from a known point, they can tell, before they begin to dig, the precise length of pump that will be required to raise the water to the surface.

Thus, if a well be sunk in one of the lowest situations in the city, as about Fleet-market, and it should be found that it there requires to be dug forty feet before water is met with, and that the well makes a sort of drawing or tapping, the water will rise in the well to the height of a certain level, where it will, of necessity, become stationary, which is at the height of about ten feet from the surface of the ground. If in St. Paul's church-yard, which by a careful level has been found to rise fifty feet above the former situation; the well in this place will require to be sunk about ninety feet before it reaches the water, and that the water will rise to the certain level, and no higher; so that there the water will require to be lifted fifty feet to reach the surface of the ground. If in a lower part of the town, as about Aldgate and Fenchurch-street, the water there is found at sixty feet, and will rise to within thirty feet of the top. If about Thames-street, and its continuations near the river, the depths to which the wells must be dug, and the distance from the surface of the ground to the water will be rather various: in some cases, the water would rise within three or four feet of the surface, and in low places, run over the top. The depth of digging will be mostly much less than in the last case before the water is reached.

A case, which is strikingly illustrative of wells where they flow over the tops, is recorded by the above writer, as having also lately occurred in the vicinity of the metropolis. A gentleman bought a house and farm a little beyond Kensington gravel-pits, on the right-hand side of the road, nearly opposite to Holland-house. The premises were entirely destitute of water, which appeared to the occupier to be so great an inconvenience, that he determined to try if he could find any there by sinking a well, and resolved, rather than not succeed, to go to a very great depth. He began digging, and went down very far without discovering any symptoms of water; but not discouraged by this circumstance, he still proceeded. At length, when he had gone very deep, he found water, and was infinitely more fortunate than he expected; for he feared that after he had found water, it would be necessary to raise it by artificial means from so great a depth, as must greatly enhance the price of

it. The water, however, rose in the well very quickly till it reached the top, and there it ran over in a very copious stream, overflowing the field around it, till it found out a level for itself, forming a living rill, that continues to flow at all times of the year. The owner of the ground, after having made of it a fine piece of water for his pleasure, and supplied all his building with it abundantly, made that part of it issue through a pipe into a stone basin by the road side, for the accommodation of passengers of every sort; where it still continues to flow, running from thence along the ditch to the bottom of the eminence on which it stands; the surplus water from the pond being conveyed off by another channel.

These cases of wells are still further illustrated and explained by the nature of what happens in sinking deep pits and shafts in many places for different purposes, and from the large bursts of internal waters which take place in many instances and situations. See QUARRIES, &c. *Draining of*, and *Spring-Draining*.

On the whole, the facts and statements which have been given above, may sufficiently explain and elucidate the manner in which water is supplied and obtained in the digging and forming of wells, as well as the nature and distribution of the strata by which it is conducted, contained, and forced up into them. However, in most cases, before the sinking of wells is undertaken or begun upon, the nature of the different circumstances of the particular cases should be well and fully inquired into and considered, and the probability of success coolly and maturely weighed from a nice examination of the different springs and wells in the immediate neighbourhood; as where this is not the case, much labour, trouble, and money, may often be expended to little or no purpose, and great disappointment be sustained.

WELL-Digging, the art of sinking wells, and lining them with stone or brick, that they may preserve their figure; as this operation is necessary for wells in all soils except rock. There are two methods of building the stone or brick within the well, which is called the steining. In one of these a circular ring is formed, of the same diameter as the intended well; and the timber of which it is composed is of the size of the brick-courses, with which the well is to be lined. The lower edge of this circle is made sharp, and shod with iron, so that it has a tendency to cut into the ground; this circular kirb is placed flat upon the ground, and the bricks are built upon it to a considerable height, like a circular wall. The well-digger gets within this circle, and digs away the earth at the bottom; the weight of the wall then forces the kirb, and the brick-work with which it is loaded, to descend in the earth, and as fast as the earth is removed it sinks deeper, and the circular brick-wall is increased or raised at top as fast as it sinks down; but when it gets very deep, it will sink no longer, particularly if it passes through soft strata: in this case, a second kirb of a smaller size is sometimes began within the first.

When a kirb would not sink from the softness of the strata, or when it is required to stop out water, the bricks or stones must be laid one by one at the bottom of the work, taking care that the work is not left unsupported in such a manner as to let the bricks fall as they are laid: this is called under-pruning.

Well-diggers experience sometimes great difficulty from a noxious air which fills the well, and suffocates them if they breathe it.

The usual mode of clearing wells of noxious air, is by means of a large pair of bellows and a long leathern pipe, which is hung down into the well to the bottom, and fresh air is forced down to the bottom by working the bellows.

This

This is intended to displace the damp air or gas, but is not very efficacious, because the damp air is of a greater specific gravity than pure air; so that ten gallons of fresh air is perhaps blown into the well, before two gallons of noxious air is displaced: and this probably happens because the atmospheric air is specifically lighter than the noxious air, and ascends through the latter to the top of the well, displacing but a small quantity of it. Such bellows, &c. are seldom to be procured on the spot when wanted, and are too weighty and cumbersome to carry about. If water is thrown down in a shower, it will sometimes clear the air; but this is laborious, in a deep well, to draw it up again.

The following apparatus may be used with great success in such cases; and as with fifty feet of pipe its weight amounts only to thirty pounds, it may easily be carried to any distance. Tubes of every kind being perpendicularly situated, and having their internal air rarefied, cause a current or stream of air to ascend through them. Suppose six lengths of metal pipe, each eight feet long, and two inches diameter, all made of tin plate, except the upper one, which is of copper, the better to bear the heat; let a cylindrical vessel be also made of copper, holding about two gallons, fixed fast to the upper pipe, and having through the sides of it a number of holes to admit air for the support of the fire, which is kindled within it. The vessel must be so fixed as to have at least five feet of pipe above its top.

The method of placing it in the well is, first, to lower down the bottom length, into the upper end of which, the lower end of the second length is joined, passing a wire through both to prevent their drawing apart again in holes made for that purpose; then fill the joint round with oil-putty, so as to render it air-tight. The upper end of each length of tube is wired, to prevent bending; which wiring also forms a receptacle for the putty. Then proceed in the same manner, with the remainder of the pipes, until the bottom one nearly reaches the surface of the water, but not quite. The fire-pan is to be supported on two timbers, placed for that purpose across the top of the wall, and a conical cover may be fitted over it to prevent the heat from passing away too rapidly, and to confine it to the sides of the pipe. The apparatus being thus fixed, it soon becomes filled with air of the same quality as that in the well; and as their power of gravity is the same, both the external and internal air become stationary, from which there can be no good effect. To put the experiment into execution, fill the fire-pan with lighted charcoal or wood, &c. the copper-pipe which is surrounded by the fire, being by this means heated, a rarefaction of the internal air takes place, which air by this means is lightened, and the external dense air, continuing to press with the same weight as first into the bottom of the tube, the equilibrium is destroyed, and a succession of noxious air passes up through the pipe, as through the funnel of a chimney, till the whole quantity is carried off; after which the pure air, which has in the meantime introduced itself into the well, begins to pass off by the same passage so long as the fire is continued, though the stream of air passing out of the top of the vertical-pipe seems small, yet the effect is great, because that stream consists entirely of noxious air that is required to be removed. The effect will be greater when the fire-pan is placed lower on the pipe, as by that means more external air becomes rarefied; but if the fire-pan is placed too low down in the well, the charcoal fire produces carbonic acid gas in great quantities, and renders the air in the well unfit for respiration.

WELL, in *Agriculture*, a term sometimes applied to a sort of pipe-chimney or vent-hole left in a stack, rick, or

mow of hay, or other similar materials, in order to prevent its being overheated. Such vent-holes should be avoided as much as possible in all cases, as injuring and destroying much hay about them, and being hurtful in other ways. See *STACKING Hay*.

WELLS, *Ebbing and Flowing*, in *Rural Economy*, such as have their waters rising and falling in an almost momentary alternate manner. See *SPRING*, and *WELL*.

WELLS, *Farm or Field*, in *Agriculture*, such as are dug in these situations for the use of live-stock.

Wells of this sort are of much use and convenience, as they prevent the trouble and disadvantage of driving cattle to distances for the purpose of getting water. See *POND*.

WELL, in the *Military Art*, denotes a depth which the miner sinks into the ground, from which he runs out branches or galleries, either to prepare a mine, or find out, and disappoint, the enemy's mine.

WELL, in a *Ship*, an apartment formed in the middle of a ship's hold to inclose the pumps, from the bottom to the lower deck. It is used as a barrier to preserve those machines from being damaged by the friction or compression of the materials contained in the hold, and particularly to prevent the entrance of ballast, &c. by which the tubes would presently be choaked, and the pumps rendered incapable of service. By means of this enclosure, the artificers may likewise more readily descend into the hold, in order to examine the state of the pumps, and repair them as occasion requires. *Falconer*.

WELL of a *Fishing Vessel*, an apartment in the middle of the hold, which is entirely detached from the rest, being lined with lead on every side, and having its bottom pierced with a sufficient number of small holes, passing also through the ship's floor, so that the salt-water running into the well is always kept as fresh as that in the sea, and yet prevented from communicating itself to the other parts of the hold. *Falconer*.

WELL also implies in the same range, or even with a surface.

WELL-*Drain*, in *Agriculture*, that sort of vent or discharge for the wetness of land, which is constructed in somewhat the well or pit manner. See *WELL-Draining*, and *SPRING-Draining*.

WELL-*Draining*, that means of clearing lands from wetness which, in certain flat situations, is accomplished by making large deep pits or wells, and the constant or occasional use of suitable machinery. In the execution of the business of forming a draining well in loose ground, a strong wooden frame is necessary to be sunk, as the work of digging the well or pit proceeds; the sides of which being made, so as in the end to be sufficiently open or permeable, to admit the water to enter freely within it, and close enough to prevent grosser matters from interrupting the machinery; especially when of the mill kind. The size of the frame for this purpose must, consequently, be adapted and suited to the nature of the engine which is employed. The laves of a mill, it has been observed, would require a length of frame, which must necessarily be proportionally strong; but, that for a pump, a frame of inconsiderable expence would be sufficient; whether of wood or uncemented brick-work.

In this sort of draining, which is applicable in many cases of cold wet flat lands lying in the valley-tracts in most parts of the country, the wetness is drawn off by these sorts of powerful machinery, working in the spring time, after wet seasons, or at other periods when necessary or wanted. See *SPRING-Draining*.

WELL-*Grown*, in *Ship-Building*, implies, that the grain of the wood follows the shape required, as in knee-timbers, &c.

WELL-

WELL-Hole, in *Building*, is the hole left in a floor, for the stairs to come up through. See **STAIRS**.

WELL-Room, of a *Boat*, denotes the place in the bottom where the water lies, between the ceiling and the platform of the stern-sheets, from whence it is thrown out into the sea with a scoop. Falconer.

WELL-Water. See **WATER**.

WELLAND, in *Geography*, a river of England, which passes by Stamford, Market Deeping, Spalding, &c. and empties itself into the German sea, in what is called "The Wash," between the counties of Lincoln and Norfolk.—Also, a river of Canada, which runs into the Niagara, between lake Erie and lake Ontario.

WELLE CORONDE, *Sandy Cinnamon*, a name given by the Ceylonese to a species of cinnamon, which feels hard and gritty between the teeth, as if it were full of particles of sand, though in reality there is no sand among it.

The bark of this tree comes off very easily: but it is not so fit to roll up into quills as the right cinnamon, for it is more rigid and stubborn, and apt to burst open. It is of a sharp but bitterish taste. The roots of all the cinnamon trees yield more or less camphor, but this as small a quantity as any of them. Phil. Trans. N^o 409.

WELLES, in *Geography*. See **WELLS**.

WELLESCHIN, a town of Bohemia, in the circle of Bechin; 10 miles S. of Budweis.

WELLESMITZA, a town of Servia, on the Danube; 10 miles S.E. of Orsova.

WELLFLEET, a township of Massachusetts, in the county of Barnstable, containing 1402 inhabitants, with a large harbour near Cape Cod. The inhabitants own 25 vessels, from 30 to 100 tons, employed in the whale, cod, mackarel, and oyster fishing; 60 miles by water S.E. of Boston.

WELLFLEET Bay, a bay of the state of Massachusetts, on the E. side of Cape Cod Bay.

WELLIA TAGERA, *H. M.* in *Botany*, a siliquous plant of Malabar, with a pentapetalous flower, and long flat pods, with transverse partitions between the contained seeds. It grows to the ordinary height of a man, with a stem as big as a man's arm, and is transplanted into gardens only on account of its beauty. It is an evergreen.

All the parts of this plant, the root excepted, are exhibited, with an addition of cummin, white sugar, and milk, against a virulent gonorrhœa. The leaves boiled in cow's milk, or used in baths, expel the gout. The bark, triturated with sugar and water, is proper for the diabetes. The bark of the root, and green saffron mixed with milk, give relief under the nodous gout, called by the Malabarians *sonida badda*. Raii Hist. Plant.

WELLIBALDSBURG, *St.*, in *Geography*, a town and citadel of Bavaria, in the bishopric of Aichstat, near Aichstat.

WELLIN, a town of Bohemia, in the circle of Koniggratz; 16 miles S.W. of Biezow.

WELLINGBOROUGH, a market-town in the hundred of Hamfordhoe, and county of Northampton, England, is principally situated on a red sand-stone rock, of which material the houses are generally built. The town is disposed along the slope of a hill, nearly a mile to the north of the river Nen, 11 miles N.E. by E. from the county-town, and 68 miles N.N.W. from London. It appears to have been of some note in the Saxon times, when a great part of it was destroyed by the Danes. After the Norman Conquest, it occurs among the numerous possessions annexed to the abbey of Croyland, in Lincolnshire; and at the suit of the monks of that house, was constituted a market-town, by

a charter from king John. In July 1738, it is stated, that about eight hundred dwelling-houses, besides outhouses, &c. were consumed by fire. A new town has been raised, and now assumes a much more respectable appearance than before the conflagration. The church is a spacious edifice, having at its west end a tower, surmounted by a spire: the roofs of the aisles, chancel, and chantry chapel, are decorated with various carved work; and on each side of the chancel are three stalls similar to those in cathedral choirs: the eastern window is richly ornamented with tracery, and sculpture in stone. This church had a guild to the honour of the Blessed Virgin; the revenues of which fraternity were, in the second year of Edward VI., appropriated to the erection and endowment of a free grammar-school. Here are also a large charity-school, and two meeting-houses for the public worship of Independent Dissenters. A weekly market is held on Wednesdays; and three fairs annually. The chief source of traffic is corn, the market for which is greatly improved by the decay of that of Higham-Ferrers, at four miles distance. Here is also a considerable manufacture of lace; as also of tammies, harrateens, and other worsted stuffs. In the population return of the year 1811, the inhabitants of this parish are enumerated as 3999, occupying 749 houses. About half a mile north-west of the town, in an open field, is a chalybeate spring, called Red-well, formerly much celebrated for its medicinal virtues: in the year 1626, king Charles and his queen resided here a whole season, for the benefit of drinking the water, pure from the source.—*Beauties of England and Wales*, vol. xi. Northamptonshire; by the Rev. J. Evans, and J. Britton, F.S.A. *Bridges's History of Northamptonshire*, 2 vols. fol. 1791.

WELLINGTON, a large market-town in the hundred of Kingsbury West, and county of Somerset, England, is situated on the borders of Devonshire, at the distance of 20 miles W.S.W. from Somerton, and 149 miles in the same bearing from London. The earliest historical account of it commences with the reign of Alfred, who bestowed the manor on Asser, who had been tutor to several of his children, and was afterwards advanced to the see of Sherborne, and died possessed of that dignity, in the year 883. After his death, the king granted the manor to the first bishop of Wells, for the support of the episcopal honours of himself and his successors. It continued annexed to that see, till the reign of Edward VI., when it became the property of the duke of Somerset by purchase from bishop Barlow. The town consists of four streets, the principal of which, called the High-street, is very wide and spacious; the houses are in general well built and commodious. It is a place of considerable trade: the chief articles manufactured here are, ferges, druggets, and pottery. A weekly market, on Thursdays, is well supplied with all kinds of provisions; and two fairs are annually held. According to the population return of the year 1811, the parish contained 755 houses, and 3874 inhabitants, of whom 565 families were stated to be employed in trade and manufacture. The church is a spacious structure, consisting of a nave, chancel, two aisles, and two small chapels. At the west end is a fine embattled tower, a hundred feet in height, decorated with twelve pinnacles of excellent workmanship. In the south chapel is a magnificent tomb in honour of sir John Popham, lord chief justice of England, in the reign of queen Elizabeth. On the table of this monument are the effigies of sir John and his lady, under an arched canopy, richly ornamented with the family arms, roses, paintings, and obelisks. The whole is supported by eight columns of black marble, five feet high, with Corinthian capitals, green and gilt. Sir John was a munificent patron to Wellington:
among

among other benefactions, he erected an hospital for six men and six women, being old and infirm; two children were also to be educated here. This edifice is still standing: fir John endowed it with an estate in land, which is vested in governors, and properly applied.—*Beauties of England and Wales*, vol. xiii. *Somerfetshire*. *Collinson's History of Somerfetshire*, 3 vols. 4to. 1791.

WELLINGTON, a small market-town in the Wellington division of the hundred of Bradford, and county of Salop, England, is situated near the Wrekin-hill, at the distance of 12 miles E. by S. from Shrewsbury, and 151 miles N.W. from London. It is neatly built, and contains many good houses. The market, which is held on Thursdays, is well supplied, and much frequented; and here are three annual fairs. The church, which has been lately rebuilt, is supported on cast-iron pillars, and the window-frames are of the same material, which gives a lightness to the edifice: one of the frames is fifteen feet in height. Near the church is a very respectable charity-school. In this town and its vicinity, at the commencement of the civil war, king Charles, then on his march to Shrewsbury, mustered his forces, and after issuing orders for the observance of strict discipline, made a solemn protestation that he would defend the established religion, govern by law, and preserve the liberty of the subject; and that if he conquered he would uphold the privileges of parliament. The parish of Wellington includes, besides the town, six townships. The return of the year 1811 states the population to be 8213; the number of houses 1724. The chief employment of the inhabitants is in the coal-works; here are also some mines of iron-ore. About two miles southward from the town is the Wrekin, a stupendous mountain 1100 feet in height. Through the adjacent country runs the Roman road called the Watling-street.

Beneath the Wrekin, and adjoining the road leading to Shrewsbury, is Orleton, the seat of William Cludde, esq. of an ancient family in this county. The mansion at present has a modern appearance, but is of very great antiquity, and till of late was enclosed with walls and a gate-house, and was surrounded by a moat.—*Beauties of England and Wales*, vol. xiii. Salop; by J. Nightingale, and R. Ryland, 1811.

WELLINKOVEN, a town of Germany, in the county of Mark; 6 miles W. of Schwitz.

WELLOE, (THE,) a rock in the English channel, near the coast of Cornwall; 9 miles S.E. of Penzance. N. lat. 5°. W. long. 5° 14'.

WELLS, WILLIAM CHARLES, F.R.S., I. and E., licentiate of the Royal College of Physicians, London, and one of the physicians to St. Thomas's Hospital, in *Biography*, was the son of parents who left Scotland and settled in Carolina, in 1753, and born in Charlestown, South Carolina, in May 1757. Few lives have been more diversified by incident and more sedulously devoted to literary and scientific pursuits, and therefore more entitled to notice in our biographical sketches than the subject of this article. Before he had attained the age of seven years, he was sent to a considerable grammar-school at Dumfries, where he remained nearly two years and a half; and in the autumn of the year 1770 he removed to Edinburgh, and attended several of the lower classes of the university. At this early age he had the good fortune to become acquainted with Mr. David Hume and sir William Miller, now known by the title of lord Glenlee, whose friendship he afterwards cultivated and valued, and whose kind offices he gratefully acknowledged. In 1771 he returned to Charlestown, and was apprenticed, in the medical profession, to Dr. Alexander Garden, whose name is well known among naturalists; and during three years of the

time he was with this gentleman, he pursued his studies with such diligence, that he acquired perhaps more knowledge than in any three subsequent years of his life. Soon after the commencement of the American war, in 1775, he came to London. The occasion of his removal was his refusal, from conscientious motives, to sign a paper denominated "The Association," which was drawn up in order to unite the people in a resistance to the claims of the British government. At the commencement of the winter of that year he went to Edinburgh, and entered upon his medical studies, with the view of taking a degree. To his former two friends, with whom he had kept up a regular correspondence, he had now the happiness of adding a third, no less intimate and constant than the others, the present Dr. Robertson Barclay. Having pursued his studies for three winters, and passed his preparatory trials in the summer of 1778, he left Edinburgh without graduating, and returned to London, where he attended a course of Dr. William Hunter's lectures, and became a surgeon's pupil at Bartholomew's hospital. In 1779 he went to Holland as surgeon to a Scotch regiment, in the service of the United Provinces; but receiving offensive treatment from the commanding officer, he resigned his commission, and challenged the aggressor, under the unjust charge of military insubordination, for which an attempt was made to punish him; but without receiving the satisfaction which he demanded, he went to Leyden in the beginning of the year 1780, and there prepared an inaugural thesis on the subject of "Cold," which was published at Edinburgh in the close of that year, on occasion of his taking the degree of doctor in medicine. At this time he commenced his acquaintance with Dr. Lister, a gentleman no less distinguished for his integrity and liberality than for his skill in his profession; and it redounds in no small degree to the honour of Dr. Wells, that their friendship continued without interruption till his death. Nor was it less honourable to both these gentlemen, that they were introduced to an acquaintance with each other by their common friend Dr. James Currie, the author of "Medical Reports," and the biographer of Burns; whose premature death was lamented by all who knew him, and were duly apprized of the eminent rank which he occupied in the medical profession. In the beginning of the year 1782 Dr. Wells visited Carolina, then in the possession of the king's troops, for the purpose of arranging the affairs of his family; and whilst he was there, he sustained a variety of offices, seemingly very incompatible with each other, and which no person destitute of his versatile talents and peculiar activity could have satisfactorily performed. He was an officer in a corps of volunteers, a printer, a bookseller, and a merchant, a trustee for the management of the affairs of some of his father's friends in England, and on one occasion a judge-advocate. In December 1782, when the king's troops were obliged to evacuate Charlestown, he removed to St. Augustine, in East Florida, and there edited the first weekly newspaper that had been published in that country, having brought with him a printing-press, which had been taken to pieces for the convenience of carriage, and which he contrived, with the assistance only of a negro-carpenter, to refit for use. During his residence in Florida, he became captain of a corps of volunteers, and manager of a company of officers, who had agreed to act plays for the relief of the poorest of the loyal refugees from Carolina and Georgia, and occasionally an actor himself. In 1784 he removed from St. Augustine to London, and becoming acquainted with Dr. Baillie, commenced an intimate, steady, and affectionate friendship, the benefits of which he experienced till his death. Having spent three months at Paris in the year 1785, he returned to London in
the

the autumn of that year, and settled as a physician in this city. His father had resided in London from the commencement of the American war, and had amassed a fortune of 20,000*l.*; but by misfortunes in trade his circumstances were now embarrassed, so that Dr. Wells, at the outset of his profession, was obliged to raise money by loans, amounting to 600*l.* For the first few years after settling in London he scarcely took a fee, and after having been engaged for ten years in the exercise of his profession, his receipts from every source did not amount to 250*l. per annum.* However in the next five years he was able to pay part of his debt, and before his death he had the satisfaction of having paid the whole of it, both principal and interest; and it should be mentioned to his honour, that when his income was very limited, he allowed an annuity of 20*l.* to a poor relation.

In 1788 he was admitted a licentiate of the Royal College of Physicians in London; and he took part with those who asserted their eligibility and right of admission to the class of fellows. After the decision of this claim in the court of king's bench, he applied in 1797 for examination, so that if he were found to be fit, he might be returned a fellow. But this application was unavailing; and yet about four years before his death the president of the college sent him a message, expressing a wish to know if he had any desire to become a fellow; to which he replied in the negative. In 1790 he was appointed a physician to the Finsbury Dispensary, in which connection he remained till the year 1798. In 1793 he was chosen a fellow of the Royal Society; and in 1800 he became physician of St. Thomas's hospital, having been assistant physician from the year 1798. In the year 1800 he was seized with a slight fit of apoplexy; but by adopting a very abstemious mode of living, he escaped any subsequent attack. From this time, however, his health declined.

In 1812 he commenced some experiments on dew, and after he had an opportunity of pursuing them, he wrote an "Essay" on the subject, which was published in August 1814, the year in which he was admitted into the Royal Society of Edinburgh; and in 1816 the Royal Society of London adjudged to him the honour of the gold and silver medals of count Rumford's donation for this essay. Although from the year 1814 to the commencement of his last illness his health was in some respects improved, he was afflicted with painful and threatening symptoms. These symptoms became gradually more alarming; and though in his last illness some hopes were entertained by his medical friends, Dr. Baillie and Dr. Lister, of his recovery, yet on the 8th of August he was suddenly seized, while he was sitting up, with the sensation of a tremulous motion in the chest, which he referred to the heat, from which time his illness intermitted. "After this," says his biographer, "an expectation was entertained of his recovery: His life was continued until the evening of the 18th of September 1817; and until the near approach of its termination, his mind was clear and active, and his spirits calm and cheerful."

Our limits will merely allow our enumerating his principal publications. Of his political papers we shall only mention one, which was written in 1781, by the desire of the commandant of the garrison of Charlestown, general Nesbit Balfour. The object of this paper was to shew, by military usage, and the nature of the case, that persons in the American service who, after having been taken prisoners and sent to their homes under their military paroles, and who appeared again in arms against the British government, subjected themselves to the punishment of death. This paper was frequently published in the newspapers, and it is pro-

bable that it was owing to this publication that general Balfour and lord Moira thought themselves justified in putting to death a colonel Haynes, the propriety of which act was afterwards a subject of debate in the British parliament. The philosophical pieces of Dr. Wells were the following: *viz.* "An Essay upon single Vision with Two Eyes," 1792, (see VISION, in the Addenda); "Two Letters, in reply to Dr. Darwin's Remarks in his Zoonomia upon what Dr. Wells had written in his Essay upon Vision, on the apparent Rotation of Bodies which takes place during the Giddiness occasioned by turning ourselves quickly and frequently round," 1794, contained in the Gentleman's Magazine for September and October; "A Paper upon the Influence which incites the Muscles to contract in Mr. Galvani's Experiments," 1795; "Experiments upon the Colour of the Blood," 1797; "Some Experiments and Observations on Vision," 1811; all published in the Philosophical Transactions. "An Essay upon Dew," 1811. In this essay the author has introduced new facts and ingenious observations, of which we shall give some account in our additions to the article DEW. "An Answer to Remarks in the Quarterly Review upon the Essay on Dew," and "An Answer to Mr. Prevost's Queries respecting the Explanation of Mr. B. Prevost's Experiments on Dew," 1815; "A Letter to Lord Kenyon relative to the Conduct of the Royal College of Physicians of London, posterior to the Decision of the Court of King's Bench, in the Case of Dr. Stanger;" "A short Letter on the Condensation of Water upon Glass," 1816; which three last appeared in Dr. Thomson's *Annals of Philosophy*. "Some Biographical Sketches by Dr. Wells" appeared in the Gentleman's Magazine.

Almost all his writings upon medical subjects are contained in the second and third volumes of the Transactions of a Society for the Promotion of medical and surgical Knowledge: and their subjects are,—erysipelas; the entire want of hair in the human body; the dropsy, which succeeds scarlet fever; aneurism of the aorta attended with ulceration of the œsophagus and wind-pipe; epilepsy and hemiplegia, apparently produced by a sharp projection from the inner table of the skull; tetanus; aneurism of the aorta, communicating with the pulmonary artery; enlargement of the cæcum and colon; gangrene of the cellular membrane between the muscles and skin of the neck and chest; rheumatism of the heart; red matter and serum of the blood in the urine of dropsy, which has not originated in scarlet fever; and observations on pulmonary consumption and intermittent fever, chiefly as diseases opposed to each other, &c.; to which may be added, a case of aphonia spasmodica, in the second volume of *Medical Communications*. His manuscript papers were directed to be destroyed, with the exception of one, relating to the difference of colour and form between the white and negro races of men, which will be published.

The literary productions of Dr. Wells have sufficiently established his reputation as a learned and skilful physician, as an acute and inventive philosopher, and as a perspicuous, vigorous, and elegant writer; and it is said, that those who knew him personally estimated him much more highly than persons who were acquainted only with his writings. His mental powers were strong, acute, comprehensive, and versatile; and he was capable of the most close and long-continued attention, and of directing this attention at pleasure. Although he was not eminently distinguished as a classical scholar, or as a deep mathematician, he had read some of the Greek and most of the Latin classics with great attention; wrote Latin with facility and correctness; and made himself

master of the elementary books of the inferior branches of the mathematics. He was well acquainted with natural philosophy, and particularly optics, and also with the facts of modern chemistry; he was an acute metaphysician, and intimately versed in the theories of morals and politics, in ancient and modern history, commerce, and political economy; he had successfully studied belles lettres, and was familiar with the best writers in the English language; and his own style was pure, perspicuous, and occasionally forcible and elegant. In conversation he was instructive and interesting; and in active life prompt and decisive, and at the same time prudent and cautious. In his habits and manners, he was indefatigable in his application; frugal, and yet as far as his circumstances would allow liberal; high-minded, but sensible of obligation and grateful for kindness; resentful, yet placable; irascible even on trivial occasions, but exercising self-command under great provocations when the importance of circumstances and propriety required it; indignant at insolence and oppression, and regardless of all personal consequences in expressing his resentment, but submissive to the appointments of heaven, and calm and cheerful under the sufferings which flowed from them. "A sense of duty," says his biographer, "was the paramount feeling of his mind, to which other passions gave way, and which danger and difficulty served only to make more active and vigorous." Such is the tribute which has been evidently dictated by a friend; and yet we have reason for being assured that it is, upon the whole, such as the merit of Dr. Wells justly claimed. *Gent. Mag.* for November 1817.

WELLS, in *Geography*, a city of Somersetshire, England, is situated in the hundred of Wells-forum, at the distance of 18 miles from Bath, 21 miles from Bristol, and 121 miles W. by S. from London. It is said to owe its origin to a remarkable spring called St. Andrew's well, the waters of which were supposed to possess extraordinary medicinal properties. These are recorded to have been highly beneficial to Ina, king of the West Saxons, whose religious zeal therefore prompted him to found a collegiate church here in the year 704, and which he dedicated to the above saint. This church was converted into a cathedral in the year 905, when three new bishoprics were constituted by order of king Edward the elder, and Wells was then made an episcopal see. This was afterwards transferred to Bath by bishop Villala, about the end of the eleventh century, who built a palace there, and assumed the title of bishop of Bath. Great contentions soon arose between the two chapters of Bath and Wells, respecting the right of election to the episcopal office. The matter being referred to the arbitration of the bishop himself, it was determined that his successors should take their title from both churches; that an equal number of delegates from both chapters should enjoy the privilege of voting, and that the installation should take place in both cathedrals. This regulation, which was made by bishop Robert, about the year 1135, continued until the reign of Henry VIII., when an act of parliament was passed for vesting the power of election solely in the dean and chapter of Wells. Henceforward the cathedral and episcopal seat have been fixed at Wells, but the title of the bishop is of "Bath and Wells." To the pious zeal of its bishops, the city is indebted for that truly interesting structure, its cathedral church. The building of king Ina having, in the course of four centuries, fallen into a dilapidated state, was about the year 1150 rebuilt on a much larger scale by its bishop. In 1239 it received considerable additions by bishop Joceline, who altered, or fitted up the choir, and made other improvements; the south-west tower was added by bishop

Harewell, and other contributors, in 1366; in 1415 the north-west tower was raised by bishop Bubwith; and finally, the chapel of the Virgin Mary was added by bishop Beckington, about the year 1445. Other parts of this interesting fabric were erected and adorned by other prelates, but the precise time of these alterations is not recorded. The cathedral, as it now appears, consists of a nave, with two aisles, a transept, and choir, also with side-aisles; at the eastern extremity of the choir is a smaller transept, and the chapel of the Virgin; on the north side is a porch, also a covered passage to the chapter-house and deanery. Over the intersection of the nave and transept is a large quadrangular tower, 160 feet in height, resting on four broad arches, and at the west end are two other towers. The length of the nave is 190 feet; of the choir to the altar, 108; and of the chapel of the Virgin, 52 feet. The whole fabric exhibits specimens of the different styles of architecture which prevailed between the twelfth and fifteenth centuries; but the most interesting part is the west front, certainly one of the most imposing examples of architectural and sculptural workmanship in the kingdom. It is adorned with a great number of niches and canopies, with statues of the apostles, popes, princes, bishops, &c. It is divided into five portions in height by bold buttresses, and four decided compartments, horizontally. In the centre is a large entrance door-way to the nave, over which are three tall lancet-shaped windows; above these is a pyramidal façade to the gable of the roof, crowned with pinnacles, and adorned with numerous niches, statues, &c. The buttresses are likewise covered with panelling, tabernacles, and statues. The interior of the church is full of interest and beauty. Its nave consists of nine clustered columns on each side, supporting pointed arches, over which is a triforium, or open gallery. A third story above this displays a series of windows, which, with the other arches, are mostly of the lancet-shape. The columns, cross-springers under the roof, and the whole architecture of this part of the church, display the style of the early part of the thirteenth century. In the nave are two elegant monumental chapels, or oratories, to the respective memories of bishops Bubwith and Knight. Adjoining the latter is a curious stone pulpit. At the intersection of the nave with the transepts is a large central tower, which rests on four solid piers, or clustered columns, sustaining four arches, and over which are inverted arches. The choir is richly ornamented, and lighted by six highly pointed windows on each side, and a large eastern window over the communion-table. Behind the latter are three open arches to the lady chapel, which is singular in form, decoration, and character. Immediately behind the altar is a circular arrangement of columns, east of which is an absis, forming a half octagon. The whole is surrounded by large windows, with painted glass. In this part of the church are several curious and interesting monuments. North of the great transept is the chapter-house, an octangular apartment, in the centre of which is a lofty clustered column, from which diverge several ribs.

Southward from the cathedral is the episcopal palace, which has more the appearance of a fortified castle than of the residence of a bishop. It is surrounded by a wet moat, an embattled wall, flanked with semicircular turrets, with a venerable gate-house on the north side. The deanery-house is a spacious quadrangular building; and here are good houses for the prebendaries. The establishment of the cathedral consists of a bishop, a dean, twenty-seven prebendaries, nineteen minor canons, a precentor, treasurer, chancellor, and three archdeacons; a number which few other cathedrals have.

The city of Wells is seated in a valley, surrounded by lofty hills, and has some spacious streets. It was first made a free borough in the reign of Henry II., by the interest of Joceline, its bishop. It afterwards received a charter from king John, by which it was provided with a weekly market; by queen Elizabeth's charter, the corporation consists of a mayor, recorder, seven masters, and sixteen common-council men. Wells has sent two members to parliament from the earliest period: the right of election is in the mayor, masters, burgesses, and freemen. The voters are about five hundred; the mayor is the returning officer. By the return to the population act of the year 1811, the number of houses is stated to be 930; of inhabitants 5156. Six annual fairs are held here; and markets on Wednesdays and Saturdays. The corporation have a spacious town-hall for the dispatch of their business; where also the assizes are held. Under this hall is an hospital, founded by bishop Bubwith, for the maintenance of thirty poor men and women. Here are several other alms-houses, particularly those endowed by Nathaniel Steel and son, for thirty-two men and women, who are allowed three shillings each *per week*, with a great-coat for the men, and a gown for the women, once in two years. A charity-school was also erected here for twenty boys and twenty girls, in the year 1714.

Near the village of Wookey, which is situated about two miles north-west from Wells, is a remarkable cavern, called Wookey Hole. In its front is an assemblage of vast rocks, which rise to the height of at least two hundred feet, almost covered with trees and plants springing out of the fissures. On the left side of a deep ravine is a natural terrace, which leads to the mouth of the cavern, and through the middle of it runs a clear rapid rivulet, that rushes out of an arch thirty feet in height, and forty in breadth, impetuously making its way over an irregular bed of rocks. Hence, an opening not more than six feet high, conducts into a spacious vault, eighty feet in height, entirely covered with stalactites. Near this is a similar, though smaller vault; and beyond them, a low passage leads to a space nearly circular, and about one hundred and twenty feet in diameter, with a vaulted roof forty feet in height. Near this area is what the vulgar call the Witch's Brewhouse, where a great number of singular configurations of stalactite are observable, to which correspondent appellations have been given, such as the boiler, furnace, &c. To the left is what is called the hall, which is very lofty, the centre of the roof being at least one hundred feet above the ground. The whole length of the cavern is supposed to be six hundred feet.—Collinson's History of Somersetshire, 3 vols. 4to. Maton's Observations on the Western Counties, 1797. Davis's Concise History of the Cathedral Church of Wells, 1809.

WELLS, a township of New York, in Montgomery county, erected in 1805 from the N. part of Northampton and Mayfield, bounded N. by Franklin county, E. by Essex, Washington, and a small part of Saratoga county, S. by Northampton and Mayfield, and W. by Johnstown, about fifty-five miles long and eight miles wide. The country is rough and mountainous, and the soil light, sandy, and barren. It has numerous lakes and ponds, which abound with trout and other cold-blooded fish, affording good food as well as sport for the angler. Pezeeke lake bears the name of an Indian, and lake Pleasant is a pleasant lake, with a fine beach of white sand.

WELLS, a sea-port town of England, in the county of Norfolk, with a harbour at the mouth of a small river, of difficult access, on account of the shifting sands at the entrance. The chief trade is in corn, malt, and coals; and of late an oyster-fishery has been established: it has no market.

The population in 1811 was 2683. Near on the W. of Wells is Holkham-hall, the magnificent seat of T. W. Coke, esq. M.P. Wells lies 118 miles N.E. from London.—Also, a town of West Florida, situated on the W. side of St. Andrew's bay. N. lat. $30^{\circ} 25'$. W. long. $85^{\circ} 50'$.—Also, a town of America, in the district of Maine, and county of York, at the bottom of a bay to which it gives name, between Capes Porpoise and Neddik, containing 4489 inhabitants; 20 miles S.W. of Portland. N. lat. $43^{\circ} 20'$. W. long. $70^{\circ} 32'$.—Also, a town of Vermont, in the county of Rutland, containing 1040 inhabitants; 10 miles S.W. of Rutland.

WELLS, a river of Vermont, which runs into the Connecticut.

WELLS'S CREEK, a river of Kentucky, which runs into the Ohio, N. lat. $38^{\circ} 47'$. W. long. $84^{\circ} 27'$.

WELLS'S FALLS, a cataract in the river Delaware; 13 miles N.W. of Trenton.

WELLS'S PASSAGE, an inlet on the west coast of North America, branching off from Broughton's Archipelago.

WELMICH, or WELMENACH, a town of Germany, in the circle of the Lower Rhine, on the right bank of the Rhine; 1 mile from St. Goar.

WELMINA, a town of Bohemia, in the circle of Leitmeritz; 5 miles W. of Leitmeritz.

WELOVAR, a town of Croatia; 16 miles S.E. of Creutz.

WELP, a town of Bohemia, in the circle of Konig-ingratz; 3 miles S.E. of Toplitz.

WELPSHOLTZ, a town of Germany, in the county of Mansfield, memorable on account of a victory which Lothario, duke of Saxony, obtained over Henry V. in the year 1115.

WELS, a town of Austria, on the river Traun. This is supposed to have been an ancient town of the Norici, and by the Romans called *Ovilara*, or *Ovilaba*. Others say it was built by the emperor Valerian after his expedition against the Scythians in Pannonia. The emperor Maximilian I. died here; 11 miles S.S.W. of Lintz. N. lat. $48^{\circ} 10'$. E. long. 14° .

WELSBACH, a river of Thuringia, which runs into the Unstrutt, near Thomabruck.

WELSCHBILLIG, a town of France, in the department of the Sarre; 18 miles N.N.E. of Luxemburg.

WELSCHBIRKEN, a town of Bohemia, in the circle of Prachatitz; 6 miles N.N.W. of Prachatitz.

WELSE, a river of Brandenburg, which runs into the Oder, near Vierraden.

WELSH GLAIVE, or BILL, in *Military Antiquities*, a kind of bill, sometimes reckoned among the pole-axes, which was formerly much in use.

WELSHPOOL, anciently TRALLWNG, a large and populous market-town, partly in the hundred of Pool and partly in that of Cawrse, in the county of Montgomery, North Wales, is situated on the bank of the river Severn, 8 miles N. from the county-town, and 169 miles N.W. by W. from London. It consists of one long and spacious street, with another smaller, crossing it at right angles, and several other collateral branches of lesser dimensions; and is the largest and best-built town in the county. From the manners and language of the inhabitants, it has every appearance of an English town; the Welsh being spoken here by few persons. An air of urbanity and opulence pervades the place, chiefly owing to the intercommunication with the more polished parts of the kingdom, and to the extensive trade in flannels; great quantities of which are manufactured here,

here, and still greater brought from the hill countries. This being the principal mart for that article, a market is held on every alternate Monday for the sole purpose of exposing it to sale. A weekly market is also held on Mondays for provisions; and here are six annual fairs for horses, sheep, and cattle. The Severn becomes navigable at a small distance below the town, at a place called the Pool-stake; and a branch of the Ellesmere canal running near, tends to facilitate carriage by water conveyance. Among the recent improvements made in the town, is the county-hall, erected at the expence of a few private gentlemen. This structure, with a colonnade and pilasters of stone in front, consists of upper apartments for the administration of justice, and of lower ones for the accommodation of trade. Beneath is a spacious place, appropriated as a corn-market; a separate space for the sale of miscellaneous articles; and an ample court for holding the assizes or great sessions. On the second floor is the county-hall room; and a handsome room adjoining is fitted up for the use of the grand jury. The church, though in the pointed style, is apparently of no very remote antiquity. It stands singularly at the bottom of a hill, and is so low, that the ground of the cemetery almost equals the height of the building. Among the sacramental utensils is a chalice of pure gold, brought from Guinea on the coast of Africa, containing a wine quart: it bears a Latin inscription, stating that its intrinsic value was 168*l.*, and that it was presented to the church in the year 1562 by Thomas Davies, some time governor-general of the English colonies on the western coast of Africa. Welsh-Pool has a very ancient corporation: its original charter was granted by one of the princes of Powys Land, about the end of the eleventh century; the present was a grant from Charles II., by virtue of which the town is governed by two bailiffs, a high steward, recorder, and town-clerk; under whom are two serjeants at mace. The population of the parish, which includes nine adjoining townships, was in the year 1811 returned to parliament as 2779; the number of houses as 578. Formerly the town contributed with the borough of Montgomery in sending a member to parliament; but was disfranchised of this privilege in the year 1728. There are some encampments in this parish, one of which is said to have been the British camp of Caractacus, on the summit of the Bryddin-hill, where the last remains of ancient British liberty were lost by the surrender of that brave sovereign: on the centre of this mountain a column was erected, to perpetuate the memory of admiral Rodney's celebrated victory over the French fleet in the West Indies, April 12. 1782.

About a mile to the southward of Welsh-Pool, is Powys Castle, formerly the chief mansion of the Convinian Welsh princes of Powys, and now the residence of the earl of Powys. This venerable pile, situated in a well wooded park, is built in the ancient style of domestic architecture, participating of the castle and mansion. The entrance is by a gateway between two massy circular towers, into the area or court, round which the apartments range. Several other towers are still standing, flanked with semicircular bastions. In front, two immense terraces, rising one above another, form the ascent, by means of a vast flight of steps. The interior exhibits little worthy of notice, excepting the principal gallery, measuring 117 feet in length, which was originally much longer; but in the modernizing plan a large room has been taken from it. The park is formed of spacious lawns, and swelling hills; the oak, beech, and chestnut, diversify the views in rich variety; and highly contribute to render the place interesting to the lovers of forest scenery. It is, however, to be regretted, that this

venerable castle is verging to decay: the buildings are in a state of dilapidation; the gardens and grounds are neglected; and the pride and ornament of the park removing, for the sake of the timber: so that at no very distant period, the beauty and magnificence of Powys may be no more.—*Beauties of England and Wales*, vol. xvii. North Wales. By Rev. J. Evans, 1812.

WELSTEIN, a town of France, in the department of Mont Tonnerre; 7 miles E.S.E. of Creutznach.

WELSUN, a town of the duchy of Guelderland; 6 miles W. of Hattem.

WELT-ROOT, in *Agriculture*, a term that signifies the dying away or falling off of wheat-crops, in some cases, in the winter or early spring seasons. It has been supposed to occur the most frequently where the wheat-crops have been put in on clover leys. Some incline to think that it depends upon the want of a sufficient degree of closeness and firmness in the soils on the beds of mould into which the crops have been put; as where they lie too open and in too porous a state, due nourishment and support is not supplied to the young wheat plants from below, that, of course, they do not form their roots in a proper manner. See TREADING.

The term is also applied to an operation in the harvesting of grain. See ROOT-*Welt*.

WELTENBURG, in *Geography*, a town of Bavaria, on the right side of the Danube; 20 miles E.N.E. of Ingolstadt.

WELTERSBERG, a town of Germany, in the county of Lemingen; 1 mile S. of Welterburg.

WELTZENEN, a town of the duchy of Westphalia; 5 miles N. of Werl.

WELWARN, a town of Bohemia, in the circle of Schlan; 8 miles N.E. of Schlan. N. lat. 50° 18'. E. long. 14° 24'.

WELWIN, a village of England, in the county of Herts, where the general massacre of the Danes is said to have begun in 1012. In this place, Dr. Young, who was the rector, wrote his celebrated *Night Thoughts*. Here is a chalybeate spring; 25 miles N. of London.

WELZHEIM, or WELZEN, a town of Wurtemberg, and capital of a lordship to which it gives name, on the Lein; 20 miles E. of Stuttgart.

WEM, a market-town of Whitchurch division of the north part of the hundred of Bradford, in the county of Salop, England, is situated near the source of the river Roden, at the distance of 7 miles S. from the town of Whitchurch, 10 miles N.E. from Shrewsbury, and 172 miles N.W. from London. From its situation Horsley infers, that it is the site of the ancient Rutunium. The manor was formerly in the possession of the earls of Arundel, but on the attainder of earl Philip, in the reign of queen Elizabeth, it fell to the crown; and James II. conferred it on the lord chancellor Jefferies, of infamous memory, who had the estate, and was created baron of Wem. On his death, the title descended to his son; but on his decease, which occurred shortly after, it became extinct. The town of Wem consists of one large street, with a few smaller ones. By the population return of the year 1811, the number of houses was stated to be 297, and the inhabitants 1395. A weekly market is held on Thursdays, and three fairs annually. The church, a rectory of the real value of about 500*l. per annum*, is a handsome edifice, with a lofty tower, and a fine chancel. A free-school was founded and liberally endowed by sir Thomas Adams, who was born in this town in the year 1586, and was elected lord mayor of London in 1645. He was an inflexible adherent to king Charles I. in his troubles, and

continued

continued his attachment to Charles II. while in exile, to whom he is said to have made a remittance of 10,000*l.* On the eve of the Restoration he was deputed by the corporation of London to go with general Monk to Breda, to conduct the king to England. The munificence and charities of sir Thomas were exemplary: among other memorials, is an Arabic professorship founded by him in the university of Cambridge. He died February 24. 1667, in the 81st year of his age. Near this town, in 1640, was born William Wycherley, a celebrated dramatic writer, who died January 1. 1715. In the same house which gave him birth, was also born John Ireland, author of the "Illustrations of Hogarth," and otherwise well known in the literary world.—*Beauties of England and Wales*, vol. xiii. Shropshire. By Rylance, and J. Nightingale, 1811.

WEMBDINGEN, a town of Bavaria; 10 miles E. of Nordlingen. N. lat. 48° 51'. E. long. 10° 40'.

WEMBERG, a town of Bavaria, in the landgraviate of Leuchtenberg; 6 miles S.W. of Leuchtenberg.

WEMDALEN, a town of Sweden, in Hardjedalen; 107 miles W.N.W. of Sundswall.

WEMISTITZ, a town of Moravia, in the circle of Znaim; 4 miles S.W. of Krumau.

WEMMERBY, a town of Sweden, in the province of Smaland; 50 miles N. of Calmar.

WEMO, a town of Sweden, in the government of Abo; 22 miles N.W. of Abo.

WEMYSS, a sea-port town of Scotland, in the county of Fife, on the N. side of the Frith of Forth; a burgh of barony governed by bailies and a council: it has a good harbour, and several vessels belong to it, chiefly employed in the carrying trade. Coals and salt are the only exports; 4 miles N.E. of Kirkcaldy. N. lat. 56° 9'. W. long. 3° 4'.

WEMYSS, *Easter*, a town of Scotland, in the county of Fife, on the coast, but without a safe harbour: here are the ruins of a castle usually called Macduff's Castle, said to have been built by Macduff, who was created earl of Fife, in 1057, by Malcolm Canmore; 5 miles N.E. of Kirkcaldy.

WEN, in *Surgery*, an encysted swelling, the particular nature of which is described in the article TUMOURS. See also ATHEROMA, MELICERIS, and STEATOMA, which are technical names applied to the three principal varieties of encysted tumours. Scarpo's observations on encysted swellings of the eye-lids, will be found in another place. See EYE-LID.

WEN, in *Animals*, a fleshy substance growing out of any part of an animal's body, and which not unfrequently proceeds from blows, bruises, strains, and other slight accidents of the same nature, most commonly beginning or taking its origin in the skin of some part, and gradually enlarging by a continual accumulation in the diseased part, until by time it becomes of a very considerable size in some cases.

Enlargements of this nature are seldom painful, and in many instances they are of several years duration before they ever reach any great magnitude; becoming quite indolent and somewhat like the natural flesh, having rarely any other sensible effect than that of causing a deformity and weight in the parts where they happen to be situated. The substance of them is, for the most part, of a sort of fleshy and often spongy nature, though, in some cases, there is a kind of sponginess mixed with a degree of hardness, and occasionally a scirrhous or cancerous disposition accompanies them, especially when they take place in the

neighbourhood of parts which are of the more glandulous kind.

In most real cases of this nature, the wen is contained in a sort of cyst or bag, which arises from the injured vessels of the part, and is formed as it slowly advances; and which incloses the whole substance, augmenting in thickness as well as size as it increases.

In the removal and cure of cases of this sort when they make their appearance on any part of an animal's body, trials should first be made to dissolve and disperse them by proper means, such as camphorated spirituous and mercurial applications: and where this cannot be accomplished, as is often the case, the use of the knife or caustic must be had recourse to for the purpose of taking them off or destroying them. In circumstances where the wens are of the pendulous sort, and hang only by a small neck root, they may frequently be easily and conveniently removed by the use of a ligature of the same kind as is employed in taking up large blood-vessels, applying it so as that it may be capable of being gradually made tighter as there may be occasion, until the substance drops off; the part being afterwards dressed and healed by the common digestive ointment or cerate. Bathing and washing the part frequently with the tincture for wounds is also, in some cases, of great utility. See TUMOUR, and WOUND, in *Animals*.

However, in cases where wens have large broad-bottom root parts which are of a knotty stringy nature, the cure, if practicable, is to be attempted by extirpation, or the use of rather mild caustics, dressing the parts as in the case of wounds. It is sometimes the best and safest practice, however, to meddle as little as possible with wens of this sort.

When enlargements of the wenny kind take place on the legs and heels of animals, as is often the case in the horse, in the more simple kinds of them, the cure may be sometimes effected by the use of applications such as hot vinegar and alum; but in case bloody matter be extravasated, suppuration should be promoted by the use of stimulant ointments and washes, and the parts be opened when proper by means of a lancet in a suitable depending situation, the openings being dressed by the wound ointment and tincture.

In these wenny enlargements, the contents are of different kinds, sometimes watery, and at others of a fleshy or thick pasty nature; which, if care be not taken to digest well out, together with the cyst, will not unfrequently collect and fill again. In some instances, the shortest method would be to extirpate them by means of the knife, which, when well performed, and the skin properly preserved, would leave little deformity. However, some of these sorts of enlargements are best let alone, as those of the watery kind in particular, which will wear away insensibly in many instances, without any application except a little camphorated mercurial ointment.

WENS of Pearl. See PEARL.

WENBACH, in *Geography*, a river of France, which runs into the Rhine, 3 miles above Drusenheim.

WENCESLAUS, or WINCESLAUS, in *Biography*, the son and successor of Charles IV., whom he succeeded as emperor of Germany and king of Bohemia, in his 17th year. In the progress of his life, he became notorious both for cruelty and debauchery, and for the most extravagant profusion, for the means of which he had recourse to the most flagitious conduct.

His extravagance, however, became at length so intolerable, that the Bohemians, in 1396, with the advice of his

his brother Sigismund, king of Bohemia, put him into confinement; from which he contrived to escape, and again to assume the royal authority. But as he pursued the same conduct, his brother Sigismund, at the request of the people, deposed him, and he was declared regent. Wenceslaus, after having been confined successively in various prisons, made his escape from one of the towers of Vienna, and returning to Prague, recovered his kingdom. After a second marriage, his extravagance involved him in new difficulties, so that, in order to his disembarassment, he was under a necessity of selling his imperial rights to John Galeazo, who had seized the sovereignty of Milan, and other cities of Lombardy dependant on the empire. The princes of the empire became indignant, and assembled a diet in 1400, in which they formally deposed him. Professing himself happy at this event, which would afford him leisure to pay attention to the government of his kingdom, he held the crown of Bohemia for 19 years longer, more tolerable in his vices, though still unreclaimed from them. The disturbances of Bohemia, occasioned by the preaching of John Huss, occurred in his time, and he took pains to compose them. At length, whilst he was sitting at dinner, he received intelligence of a sudden tumult at Prague, which occasioned a paroxysm of rage, that was followed by an apoplexy, which terminated his life in 1419, at the age of 58. Mod. Un. Hist. Moreri.

WENDEL, in *Geography*, a town of Sweden, in Upland; 15 miles N. of Upfal.

WENDELEN, a town of Sweden, in Harjeadalen; 18 miles S.E. of Langaschantz.

WENDELL, a township of Massachusetts; 90 miles N.W. of Boston.—Also, a township of New Hampshire, in the county of Cheshire, containing 447 inhabitants; 30 miles N.W. of Concord.

WENDELSTEIN, a town of Germany, in the principality of Anspach; 8 miles S. of Nuremberg. N. lat. 48° 18'. E. long. 11° 4'.—Also, a town and ruined citadel of Thuringia; 6 miles S.W. of Querfurt.

WENDEN, a town of the duchy of Westphalia; 4 miles S. of Olpe.—Also, a town of Prussia, in the province of Bartenland; 6 miles N. of Raftenburg.

WENDIA, in *Botany*, a new umbelliferous genus, thus named by professor Hoffmann, in honour of Dr. Wendt, professor of Physic at Erlang, counsellor to the Elector Palatine, and successor to the great Schreber in the distinguished situation of President of the Imperial Academy *Natura Curiosorum*. He is celebrated for the numerous observations which he has published, respecting medicinal plants, and for his zeal in the promotion of botanical studies in general.—Hoffm. Gen. Plant. Umbellif. v. 1. 136. t. 1. B. f. 8, a, b.—Class and order, *Pentandria Digynia*. Nat. Ord. *Umbellatae*, Linn. *Umbelliferae*, Juss.

Gen. Ch. *Cal. General involucreum* none; *partial* of a few short, unequal, lanceolate or linear, deciduous leaves. *Petiole* of five unequal teeth, two of them, in the radiant flowers, twice as large as the rest, ovate, acute. *Cor. Universal* irregular; flowers of the radius perfect, fertile, except a few males which are interspersed: *partial* of five petals, with long claws; the outer ones in the radius very large, the middle one divided almost half way down into two divaricated, linear-oblong, obtuse, slightly falcate, equal lobes; lateral ones rather smaller, unequally cloven, falcate, one lobe three or four times the length of the other; inner ones much the smallest, about equal to the petals of the disk, two-lobed from their incurvation, their point ovato-lanceolate, acute, channelled. *Stam.* Filaments five, simple, equal, spreading,

the length of the smaller petals longer than the petals in the flowers of the disk; anthers nearly ovate, two-lobed. *Pist.* Germen oval, compressed, striated, hairy; styles two, erect, at length widely spreading, tapering, their base conical, winged with a membranous crisped border running down from each style; stigmas capitate, obtuse, at length somewhat globular. *Peric.* Fruit almost perfectly smooth, obovate, nearly orbicular, compressed, bordered, striated and striped, entire at the edges. *Seeds* two, uniform, emarginate, crowned, in the terminal notch, with the conical, winged, sessile base of the two deflexed permanent styles: dorsal ribs three, slender, slightly elevated, converging at each end; marginal ones two, parallel: stripes four, descending from the top of the seed between the ribs, obtuse, club-shaped, brownish, not half the length of the seed: border convex, terminating in a thin, flat, sharp edge, which is channelled externally, emarginate at the bottom.

Eff. Ch. *General involucreum* none; *partial* obsolete. Flowers radiant. Calyx unequally toothed. Fruit nearly orbicular, compressed, notched, with three ribs, and four short intermediate stripes; crowned with the styles, whose base is winged.

Obf. The want of a general involucreum, and the slightness of the partial one, added to the more orbicular form of the seeds, and their smoothness, appear to afford the chief marks of distinction between this genus and *HERACLEUM*, (see that article,) from which we should be rather unwilling to separate it, any more than *Sphondylium*.

The only species mentioned by the author is,

1. *W. Chorodanum*. Long-leaved *Wendia*. Hoffm. n. 1. (*Heracleum longifolium*; Marfch. à Bieberst. Taur. Caucaf. v. 1. 223, excluding all the synonyms.)—Native of the grassy declivities, surrounding the Caucasian mineral waters of Nartfana, flowering in July. The root is biennial. *Leaflets* two pair with an odd one. General and *partial involucreum* scarcely discernible. *Flowers* snow-white; those of the radius remarkably unequal. *Seeds* when bruised agreeably fragrant. The author of the *Flora Taurico-Caucasica* says, he thinks this more akin to *Heracleum Sphondylium*, with which Crantz and Lamarek unite it, than to the *angustifolium* of Jacquin, to which it is referred by Willdenow. The latter, however, proves to be a different plant, and it is probable that Willdenow had no knowledge of Hoffmann's *Wendia*, any more than Jacquin, Crantz, or Lamarek, all their observations referring to the real *H. longifolium* of Fl. Austrac. t. 174.—The specific name, *χοροδανον*, is an old synonym of the *Sphondylium*, or Cowparsnep.

WENDING, at *Sea*, a term for bringing a ship's head about, and seems only to be a corruption from *winding*. They say, *How wends the ship?*

WENDLANDIA, in *Botany*, owes its name, though not its distinction as a genus to the late professor Willdenow, who dedicated it to the author of that distinction, Mr. John Christopher Wendland, curator of the royal garden at Herrenhausen, "a most acute botanist, and highly meritorious writer." His name appears in the *Sertum Hannoveranum* of the very eminent professor Schrader, as the delineator and engraver of the plates of that work. These display great botanical skill and attention.—Willd. Sp. Pl. v. 2. 275. Pursh 252. ("Androphylax; Wendland Obf. 37.")—Class and order, *Hexandria Hexagynia*. Nat. Ord. *Menisperma*, Juss.

Eff. Ch. *Calyx* of six leaves. Petals six, succulent. Styles reclining. Capules six, of one cell. Seeds solitary.

1. *W. populifolia*. Poplar-leaved *Wendlandia*. Willd.

Pl. 1. Pursh n. 1. (*Menispermum carolinum*; Linn. Sp. Pl. 1468. Willd. Sp. Pl. v. 4. 825. Ait. Hort. Kew. v. 5. 404. *M. folio hederaceo*; Dill. Elth. 223. t. 178. *Androphylax scandens*; "Wendl. Obs. 38. Hort. 3. t. 16." *Cocculus carolinus*; De Cand. Syst. v. 1. 524.)—Found in hedges and woods, from Carolina to Florida, flowering in June and July. *Stem* shrubby. *Flowers* very small, greenish-white. *Berries* red. *Purf.* Hardy in the gardens of Europe, where M. De Candolle says it is very frequent, flowering in August. *Stem* twining, with round branches, striated and downy when young. *Leaves* alternate, heart-shaped, or broadly ovate, entire, tipped with a small point, rarely three-lobed; an inch and a half or two inches long, with three or five radiating ribs; downy beneath. *Footstalks* round, downy, about an inch in length. *Flower-stalks* axillary; those of the male flowers, (which are generally, not always, distinct from the female,) racemose, simple; those of the female three-cleft.

Professor De Candolle has referred this plant to his genus *Cocculus*, separated from *MENISPERMUM*, (see that article,) on account of the flowers being three-cleft, not four-cleft, to use the Linnæan language; and the stamens only six, instead of from sixteen to twenty. We cannot but hesitate to adopt a genus so circumstanced, and therefore shall say little concerning the name, which its antiquity can hardly authorize. We regret to perceive that our learned friend seems inclined to make antiquity paramount to every other consideration in nomenclature; thus assuming a principle subversive of all his own authority, which otherwise might be of sufficient weight to render the most important service to this branch of botany. We hope he will soon perceive, that sense and learning are as applicable to it as to any other part of the science, and full as necessary to preserve the whole from ruin.

If the name of *Cocculus* should be discarded, though the genus be retained, still that of *Wendlandia* can scarcely take its place; there being several others, good or bad, certain or uncertain, which have a prior claim on the score of antiquity. With these we will not here encumber our paper. The reader may find them in De Candolle.

WENDLING, in *Geography*, a town of Austria; 3 miles W. of Tauffkirchen.

WENDLINGEN, a town of Wurtemberg, on the river Lauter, near the Neckar; 12 miles S.E. of Stuttgart. N. lat. 48° 38'. E. long. 9° 27'.
